Toxoplasmosis is the most common laboratory-associated parasitic infection (48). Infection can occur through ingestion of sporulated oocysts from feline fecal specimens or through skin or mucosal contact with tachyzoites or bradyzoites in tissue or culture. All *Toxoplasma* isolates should be considered pathogenic for humans. Procedures for separating oocysts from feline feces and for infecting mice have been described; fecal concentrations should be performed before oocysts sporulate and become infectious. Laboratory equipment and glassware that have been in contact with oocysts should be sterilized, since the oocysts are not easily killed by chemical exposure. Immunocompromised-persons and *T. gondii*-seronegative women who are pregnant or might become pregnant should be counseled about the risks associated with *T. gondii* infection (e.g., central nervous system infection and congenital infection) and given the option of not working with live *T. gondii* and of not working in a laboratory in which others do so.

Of the 47 cases of laboratory-acquired toxoplasmosis, the majority were in the United States and Europe. The most common route of exposure was parenteral; however, in 10 of the cases no specific accident or route of exposure could be identified. Although 9 patients were asymptomatic, 38 were considered to be symptomatic if they had lymphadenopathy. Four individuals had encephalitis, two of whom had myocarditis, and one patient with both conditions died (18).

Specimen Handling

Another consideration involves the handling of specimens from patients with AIDS. Although the agent, HIV, is considered to be a very fragile virus that does not survive in the environment, specimen-handling precautions are advised. Some laboratories suggest that stool specimens being processed for *Cryptosporidium* (often diagnosed in AIDS patients) be handled in a biological safety cabinet and be centrifuged in capped centrifuge tubes. These types of precautions will help diminish the chances of an accidental laboratory infection.

Summary

Although there are real possibilities for health care-associated and laboratory transmission of parasites, proof of such transmission is usually very difficult to document. Depending on the area of the country and the number of endemic parasites present in the community, documentation can be particularly difficult. In areas where many organisms are endemic, it is almost impossible to differentiate between a community-acquired infection and one acquired in the work setting.

Some of the infectious agents being handled in the laboratory present a potentially more serious problem. Although many laboratories do not handle all of these agents, their personnel may still be at risk when performing certain techniques or handling certain specimens. For these reasons, it is very important that everyone become aware of possible hazards when working in the field of diagnostic medical parasitology. The information presented in Tables 31.1 through 31.3 provides specific, practical information concerning safety precautions in the laboratory.

Immunology of Parasitic Infections

- Amebiasis
- Giardiasis
- Toxoplasmosis
- African trypanosomiasis
- American trypanosomiasis
- Malaria
- Helminth infections

The ability to distinguish between self and non-self is required for a functioning immune system. It is important to remember that infection with an organism does not necessarily mean diseases, since the immune system in most cases will be able to eliminate the infection before disease occurs. Disease occurs only when the infecting load is high, when the organism is quite virulent, or when immunity is compromised. Although the immune system is beneficial to the host, there can be detrimental effects as well. During an immune response, there may be local discomfort and damage to healthy tissue as a result of the toxic products produced by the immune response. Also, in some cases the immune response can be directed toward host tissues, resulting in autoimmune disease.

The immune system is made up of two interrelated parts, the innate (nonspecific) and acquired (specific) systems (1–3). The innate immune system is the first line of defense against organisms while the adaptive immune system acts as a second line of defense and also affords protection against re-exposure to the same pathogen. Each of these major parts of the immune system uses cellular and humoral components to facilitate their protective function. The innate immune system also has anatomical features that function as barriers to infection. Although these two arms of the immune system have distinct functions, there is interplay between the two. The acquired immune system requires some time to react to an invading organism, whereas the innate immune system includes defenses that are present immediately for use. In addition, the acquired immune system is antigen specific and reacts only with the organism that induced the response. In contrast, the innate system is not antigen specific and reacts equally well to a variety of organisms. Also, the acquired immune system demonstrates immunological memory; it reacts more rapidly on subsequent exposure to the same organism.

For many years, there has been extensive research in immunoparasitology directed at the identification, isolation, purification, and characterization of parasite antigens. Antigens are required for immunodiagnosis, clarification of immunopathology, quantitation of various immune responses in the host, and evaluation of potential vaccines. Antibodies to defined antigens are used for typing of reagents, the study of antigenic variability, passive immunization, and *in vitro*

doi:10.1128/9781555819002.ch32

TABLE 32.1 Parasite antigens[a]

- I. Immunologic criteria
  - A. Importance of the induced immune response to the parasite or host (relevant or functional antigens versus incidental antigens)
    1. Host-protective antigens[b]: related to induction and expression of host-protective immunity
    2. Immunodiagnostic antigens: related to detection of antibodies, skin test sensitivity (both immediate or delayed), detection of circulating or urinary antigens
    3. Immunopathologic antigens[c]: related to induction and expression of immunopathology
    4. Parasite-protective antigens: related to induction and expression of parasite-protective immunity
  - B. Immunogenicity in different animals
    1. Natural antigens: infection of natural hosts or immunization of natural hosts with or without adjuvants
    2. Novel antigens (heteroantigens): immunization of unnatural hosts with or without adjuvants, or infection of nonpermissive hosts
  - C. Type of lymphocyte involved, e.g., T-cell-stimulating carrier determinant, B-cell-stimulating haptenic determinant, allergen, T_s-stimulating determinant
- II. Parasitologic criteria
  - A. Origin and location
    1. Soluble exoantigens: released from living parasites, parasitized cells, or cultured cell lines and called excretory/secretory (ES), excretory/secretory/tissue turnover (EST), or metabolic antigens
    2. Soluble somatic antigens: extracted from parasites or parasitized cells; may be surface or internal
    3. Dead parasites, fragments or secretory blebs
    4. Whole living parasites
    5. Body fluids of nematodes
    6. Cystic fluids of larval cestodes
  - B. Parasite population and life cycle
    1. Genus-, species-, strain-, and stage-specific antigens
    2. Molting antigens
- III. Biochemical criteria
  - A. Composition (protein, lipid, carbohydrate, glycoprotein, glycolipid, etc.)
  - B. Characteristics (size, chain structure, determinant number and type, etc.)
  - C. Molecule function (enzyme, metabolite, receptor, recognition structure, etc.)
  - D. Future sources (expression of cloned DNA, chemical synthesis, stimulation of anti-idiotypic antibodies)

[a] Data from reference 1.

[b] It is not the host antigens themselves but the immune responses that these antigens induce which are host protective.

[c] Immunopathologic immune responses depend on the genotype of the host and may also have beneficial effects.

inhibition studies. Without the use of defined antigens and antibodies, a thorough understanding of the immunologic aspects of the host-parasite relationship is unlikely. Table 32.1 contains information on the various categories of parasite antigens, while Table 32.2 lists various methods of antigen analysis.

TABLE 32.2 Methods of antigen analysis

- Gel precipitation techniques
  1. Double diffusion
  2. Ouchterlony
  3. Immunoelectrophoresis
  4. Autoradiography of precipitin lines
  5. Counterimmunoelectrophoresis
  6. Counterradioimmunoelectrophoresis
- Immunoprecipitation and gel analysis
  1. Anti-immunoglobulins
  2. Sodium dodecyl sulfate-polyacrylamide gel electrophoresis
  3. Isoelectric focusing
  4. Nonequilibrium pH gradient electrophoresis
  5. Fluorography
- Gel overlay or transfer techniques
  1. Direct application of antiserum to the surface of one- or two-dimensional gels
  2. Direct application of antiserum to a paper transfer of the gel
  3. Passive binding to nitrocellulose sheets
  4. Covalent bonding to diazobenzyloxymethyl paper
  5. Filter affinity transfer
- Identification of surface antigens
  1. Antigen labeling (intrinsic or extrinsic)
  2. Antigen solubilization
  3. Antigen fractionation
  4. Demonstration of cell surface location
- Hybridoma-derived antibodies
  1. Production of monoclonal antibodies
  2. Screening procedures for hybridoma culture supernatants
- Recombinant DNA
  1. Clarification of genomic rearrangements related to antigenic variation
  2. Identification of nucleic acid sequence data
  3. Production of potentially useful parasite polypeptides

It is important to understand the factors influencing the immune responses of the host, including (i) genetics; (ii) state of the host at exposure, including nutrition, age, health status, and underlying diseases; and (iii) the size, route, and frequency of the parasite loading dose. Also, there are several types of resistance, which include natural resistance (how refractory the host is to a particular parasite), acquired resistance (either specific or nonspecific), and immunoregulation (Table 32.3).

Innate Immune System. Anatomical barriers to infections include mechanical factors (epithelial surface physical barrier, desquamation of skin epithelium, cilia movement in air passages, peristalsis in the gastrointestinal tract, flushing of tears, and saliva), chemical factors (fatty acids in sweat, lysozyme and phospholipase in tears, saliva and nasal secretions, low pH of sweat and gastric secretions, defensins, and surfactants), and biological factors (normal flora competitors). However, once infectious agents have penetrated the anatomical barriers, acute inflammation be-

TABLE 32.3 Immunoregulatory systems in the host

Antibody-mediated mechanisms	
	Immunologic blockade
	Polyclonal B-cell activation
	Anti-idiotypic antibodies
Cellular mechanisms	
	Tolerance
	Specific suppressor cells
	Nonspecific suppressor cells

comes a factor. Humoral factors play an important role in inflammation, which is characterized by edema and the recruitment of phagocytic cells (Table 32.4). These humoral factors are found in serum or they are formed at the site of infection.

The innate response is the first to be activated during the response to invading organisms and is due primarily to phagocytic cells. This response is related primarily to immediate recognition and response to pathogen invasion. Phagocytes include polymorphonuclear leukocytes or neutrophils, monocytes, and macrophages (Table 32.4). Secondary phagocytes can include dendritic cells, fibroblasts, and epithelial cells. Macrophages are found in all tissues and represent the first line of defense against pathogenic invasion of the host (Table 32.5). In order to thrive, parasites must be able to survive the innate response. Complement activation represents a first line of defense against extracellular parasites. Once the membrane attack complex is formed, parasite lysis can occur while complement components opsonize parasites for phagocytosis. One of the most important cytokines in cell-mediated innate resistance is interleukin-12 (IL-12). IL-12 activates natural killer (NK) cells, which in turn produce gamma interferon (IFN-γ), which is responsible for activation of effector mechanisms that control replication of intracellular parasites.

Acquired/Adaptive Immune System. Although innate immunity is critical in resistance to acute parasitic infections, the acquired, or adaptive, response is necessary for long-term protective immunity. Adaptive T- and B-cell responses following infection depend on accessory cells that present antigen, provide costimulation, and produce cytokines, all of which impact the onset, duration, strength, and type of the adaptive immune response. CD4$^+$ helper T cells are divided into two subsets, Th1 (type 1 response) and Th2 (type 2 response), each of which produces different cytokines and has different functionalities (Table 32.6). At times, both type 1 and type 2 responses may be used to eliminate the same parasite. These two mechanisms may be functional at the same time, during different stages of the parasite life cycle, or in different locations within the body.

TABLE 32.4 Humoral and cellular barriers to infection (serum or at site of infection)

Immune system factor	Comments
Humoral	
Complement system	Major humoral nonspecific defense mechanism. Once activated, complement can lead to increased vascular permeability, recruitment of phagocytic cells, and lysis.
Coagulation system	Depending on the severity of the tissue injury, the coagulation system may or may not be activated.
Lactoferrin, transferrin	Plasma proteins that bind iron; expressed secretory granules of neutrophils, airway fluid, cervical mucus, breast milk, tears, saliva
Interferons	Proteins that can limit replication
Lysozyme	Breaks down organism membranes; small, abundant cationic enzymes; widely distributed; expressed in PMNs, monocytes, macrophages, keratinocytes, small intestine, tracheal epithelial cells, pneumocytes and apocrine gland secretory cells; found in tears, saliva, breast milk and respiratory fluid
Interleukins	Induce fever, production of acute-phase proteins
Cellular	
Neutrophils	Polymorphonuclear cells (PMNs) phagocytize/kill invaders; contribute to collateral tissue damage during inflammation
Macrophages	Tissue macrophages and monocytes (differentiate into macrophages) function in phagocytosis/intracellular killing; extracellular killing; contribute to tissue repair; act as antigen-presenting cells (required for induction of specific immune responses)
Natural killer (NK) cells, lymphokine activated killer (LAK) cells	Not part of inflammatory response, but important in nonspecific immunity
Eosinophils	Contain protein granules; effective in killing certain parasites

Immunopathologic Reactions in the Host. It is important to have a basic understanding of the types of immunopathologic reactions in the host which are responsible for disease. These are often classified into four categories or pathways by which the host responds. They have been categorized as (i) type I reaction (anaphylactic), initiated by the antigen reacting with tissue cells (basophils and mast cells) passively sensitized by antibody produced elsewhere (release of pharmacologically active substances); (ii) type II reaction (cytotoxic or cell stimulating), initiated by the antibody reacting with an antigenic component of, or antigen associated with, a cell or tissue element (damage occurring in the presence of complement or certain mononuclear cells); (iii) type III

TABLE 32.5 Macrophage functions

Macrophage functions	Mechanisms
Protective	
Detection of pathogen invasion	Opsonic receptors for microbes Complement and antibody receptors Nonopsonic receptors Membrane-bound pattern recognition receptors (C-type lectins, leucine-rich proteins, scavenger receptors, and integrins)
Control of microbial spread	Phagocytosis, granuloma formation, intracellular killing
Recruitment of immune cells	Release of cytokines and other inflammatory mediators
Lymphocyte activation	Antigen presentation, costimulatory molecules, cytokines
Effector cells for cell-mediated immunity	Increased phagocytosis, increased intracellular killing, clearance of apoptotic cells
Participation in humoral immunity	Receptors for antibody and complement
Nonprotective	
Tissue damage	Extracellular release of toxic oxidants, hydrolytic enzymes Inflammatory mediators (TNF-α, IL-1) Fever, wasting, septic shock
Dissemination of pathogens	Transport throughout the host
Autoimmune disease	Presentation of microbial epitopes to lymphocytes, which cross-react with self molecules

TABLE 32.6 Differences between Th1 and Th2 CD4$^+$ T helper cells

Th1: type 1 responses	Th2: type 2 responses
Produce IFN-γ and IL-2; induction of cytolytic activity by CD8$^+$ T cells; production of complement-fixing antibodies	Produce cytokines (IL-4, IL-5, IL-10, and IL-13); associated with high levels of neutralizing and cell-bound antibodies, mast cell activation, eosinophilia, suppression of type 1 responses
IL-12 associated with resistance to protozoa and susceptibility to various helminths	IL-4 plays important role in development of Th2-type responses: associated with resistance to helminths (expulsion of intestinal nematodes) and susceptibility to protozoa
Produce lymphotoxin: promote macrophage activation and generation of cell-mediated immunity	Support maturation of B cells to immunoglobulin-secreting cells (activation of humoral immune mechanisms)
Resistance to intracellular pathogens requires Th1 proinflammatory response	Resistance to extracellular pathogens requires Th2 response
Prevention: IFN-γ, IL-12, IL-10 also cooperate to keep Th2 response in check	Prevention of Th1 response from overproduction: IL-10, TGF -β, IL-4
Problems: effector molecules detrimental if produced too long: nitric oxide, reactive oxygen intermediates (IL-1, IFN-γ, TNF)	Problems: strong antibody responses = antigen/antibody complexes, complement activation, eosinophils = immediate hypersensitivity; can cause hepatic fibrosis, portal hypertension, chronic morbidity

TABLE 32.7 Allergic reactions responsible for disease in parasitic infections[a]

Infection	Clinical disease	Reaction type
Malaria	Nephrotic syndrome	Immune complex (III)
	Anemia	Cytotoxic (II)
Chagas' disease	Myocarditis	Cytotoxic (II)
Leishmaniasis	Spectral disease	Cell mediated (IV)
Schistosomiasis	Swimmer's itch	Anaphylaxis (I)
		Cell mediated (IV)
	Katayama syndrome	Immune complex (III)
	Granulomatous disease	
	Schistosoma mansoni	Cell mediated (IV)
	Schistosoma haematobium	Cell mediated (IV)
Filariasis	Elephantiasis	Cell mediated (IV)
	Tropical pulmonary eosinophilia	Anaphylaxis (I)
Echinococcosis	Leaky hydatid fluid	Anaphylaxis (I)

[a] Data from references 2 and 3.

reaction (antigen-antibody complexes), initiated when the antigen reacts with precipitating antibody (forming microprecipitates in and around small vessels, interfering with membrane function, and forming soluble circulating complexes); and (iv) type IV reaction (delayed, tuberculin type, cell mediated), initiated by reaction of active lymphocytes in response to allergen, release of lymphokines, and/or cytotoxicity (infiltration of cells). These are listed in Table 32.7. The overall immune response to the presence of any parasite is no different from the responses seen with any infectious agent, all of which begin with the organism infecting the host and being recognized by the cells of the immune system. Once the parasite is recognized as foreign by the immune system, a series of steps are initiated (Fig. 32.1; Table 32.8).

Parasites and Avoidance of the Host Immune System. Parasites have three basic characteristics that make it very difficult for the host to control them: parasite size, complicated parasite life cycles, and antigenic complexity. There are also a number of ways in which parasites avoid the host immune system responses: these include (i) location

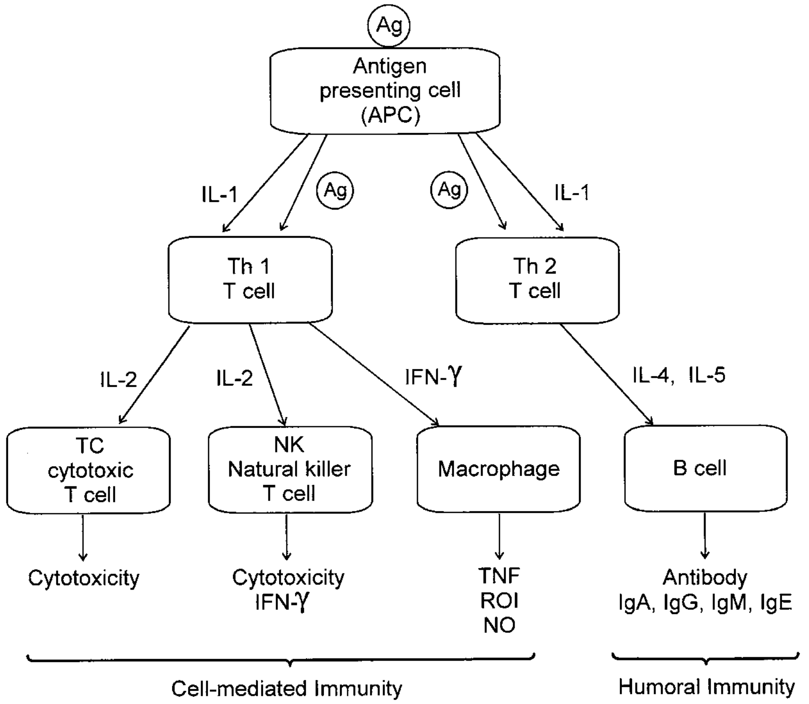

Figure 32.1 Representation of the immune response. Antigen (Ag) is recognized and processed by antigen-presenting cells (APC) and presented to Th1 or Th2 cells that carry receptors for the antigen. At the same time, the APCs release IL-1, a cytokine that activates resting Th1 and Th2 cells. Activated Th1 cells produce IL-2, which activates cytotoxic T (TC) or natural killer (NK) cells. Cytotoxic T cells kill target cells carrying the original antigen in a major histocompatibility complex-restricted way, while NK cells kill target cells nonspecifically. Another product of the Th1 cells is IFN-γ, which activates resting macrophages to become more phagocytic and to release TNF, reactive oxygen intermediates (ROI), and nitric oxide (NO). Both ROI and NO are involved in killing intracellular parasites or those in close proximity to the activated macrophage. The Th2 cells release IL-4 and IL-5, which are involved in B-cell activation and the release of antibodies specific to the antigen. IL-5 also activates eosinophils. Antibodies may cooperate with macrophages and eosinophils to serve as a bridge bringing the activated cell and the parasite together; they may also support the release of toxic molecules directly onto the surface of the parasite. *Note*: It is important to remember that some of the cytokines exert both a positive and negative influence on the immune response at the same time; this diagram is designed to show the main features of the overall immune response. (Adapted from references 2 and 3.) doi:10.1128/9781555819002.ch32.f1

within body sites that are relatively protected from the immune response, (ii) various modifications of surface antigens, and (iii) different mechanisms that can modify the host immune response. A number of these evasion mechanisms are listed in Table 32.9.

All human parasites elicit immune responses, both humoral and cellular. Specific antibodies belonging to the IgM, IgG, IgA, and IgE classes have been found, indicating the body's recognition of parasite antigens (Table 32.10). Cell-mediated immune responses have also been clearly documented. However, in both cases, there may be little or no correlation between responses and protection of the host.

The immune system functions in the same way for parasites as for other organisms; however, there are some dramatic differences based on the complexity of the response. As parasites progress through their normal life cycle stages, many different antigens are expressed at each different stage. This leads to the development of many different antibody-dependent and -independent responses. In some cases, the immune system of the host actually becomes confused, leading to situations where the host is harmed rather than helped.

Although the host response to protozoa is quite different from the host response to helminths, some general statements apply to both situations. When a parasite and the host inter-

TABLE 32.8 Immune system “alphabet soup” and definitions[a]

Term[b]	Definition	Comments
APC	Antigen-presenting cell	Processes the foreign antigen and presents it to the T-helper cells
B cell	Lymphocyte; precursor of plasma cell; expresses immunoglobulins on its surface but does not release them	B lymphocyte; short life; responsible for production of immunoglobulins
T cell	Lymphocyte; helper, killer, suppressor cells	T lymphocyte; long life; responsible for cell-mediated immunity; soluble products are lymphokines
Th	T-helper cell; both Th1 and Th2 carry same $CD4^+$ or $CD8^+$ surface markers	T lymphocyte; Th1 produces IL-2 and IFN-γ; Th2 produces IL-4 and IL-5; may be antagonism between products of Th1 and Th2; Th1 drives immune response toward antibody-independent immune responses; Th2 drives immune response toward antibody production
Lymphokine	Hormone-like peptide, released by activated lymphocytes	Mediates immune responses
Cytokine	Hormone-like low-molecular-weight protein that regulates the intensity and duration of immune responses and is involved in cell-to-cell communication	Interferon (IFN), interleukin (IL), lymphokines; released from spleen, thymus, epithelial, endothelial, and mast cells and by fibroblasts and lymphocytes
Interferon (IFN)	Small glycoproteins; classified into three groups (alpha, beta, and gamma); can regulate many cell properties and functions	IFN-α2A and -2B used as antineoplastic agents; IFN-β elaborated by fibroblasts; IFN-γ elaborated by T lymphocytes in response to specific antigen or mitogenic stimulation
Interleukin (IL)	Name given to cytokines once their amino acid structure is known	IL-1: from mononuclear phagocytes; enhances proliferation of Th and growth and differentiation of B cells IL-2: from Th; causes proliferation of T cells and activated B cells (T-cell growth factor) IL-3: from monocytes, fibroblasts, and endothelial cells; increases the production of monocytes (multi-colony-stimulating factor) IL-4: from T4 lymphocytes; causes differentiation of B cells (B-cell differentiation factor) IL-5: from T cells; causes activation of B cells and influences cytotoxic activity of eosinophils; increase in eosinophils IL-6: from fibroblasts, macrophages, and tumor cells; increases synthesis and secretions of immunoglobulins by B cells (B-cell-stimulating factor 2, IFN-β2) IL-7: from bone marrow cells; causes proliferation of B and T cells IL-8: from endothelial cells, fibroblasts, keratinocytes, macrophages, and monocytes; causes chemotaxis of neutrophils and T cells IL-9: from T cells; causes growth and proliferation of T cells IL-10: from helper T cells, B cells, and monocytes; inhibits IFN-γ secretion by T cells and mononuclear cell inflammation; controls type of immune response IL-11: from bone marrow endothelial cells, macrophages, and preadipocytes; stimulates increased concentrations of acute-phase proteins (C-reactive proteins), mannose-binding protein, serum amyloid-P component, α_{11}-antitrypsin, fibrinogen, ceruloplasmin, and complement components C9 and factor B in plasma IL-12: from B cells, T cells, and macrophages; induces IFN-γ gene expression in T cells and NK cells; controls type of immune response; facilitates formation of Th1 type response IL-13: from Th cells; inhibits mononuclear cell inflammation IL-14: from T cells; stimulates B-cell proliferation and inhibits immunoglobulin secretion IL-15: from T cells; stimulates T-cell proliferation and NK cell activation

(continued)

TABLE 32.8 Immune system "alphabet soup" and definitions[a] *(continued)*

Term[b]	Definition	Comments
NK cell	Natural killer cell; heterogeneous collection of lymphocytes; neither B nor T cells; activated by IL-12	Kills target cells nonspecifically; does not involve MHC[b] class I molecules; is being increasingly implicated in protection against parasitic infections
Cytotoxic T cell	T lymphocyte	Kills target cells carrying original antigen in an MHC-restricted manner; often involved in viral infections but seldom in parasitic infections
TNF	Tumor necrosis factor; a cytolytic factor that is produced by CD4 and CD8 T cells after exposure to antigen; also produced by macrophages	A polypeptide hormone; has the ability to modulate adipocyte metabolism, lyse tumor cells *in vitro*, and induce hemorrhagic necrosis of certain transplantable tumors *in vivo*; TNF-α influences cytotoxic activity of eosinophils
ROI, NO	Reactive oxygen intermediates; nitric oxide	Both are involved in intracellular killing of ingested parasites or destruction of parasites in close proximity to the activated macrophage

[a] Adapted from references 2, 3, 30.
[b] MHC, major histocompatibility complex.

TABLE 32.9 Various methods used by parasites to evade the host immune response

1. Become intracellular (*Plasmodium* spp.)
2. Enter immunologically protected site soon after infection (*Plasmodium* spp.)
3. Leave site of established immune response during life cycle (*Ascaris lumbricoides*)
4. Become disguised with host antigen(s) (*Schistosoma* spp.)
5. Survive in macrophages (*Leishmania* spp., *Trypanosoma cruzi*, *Toxoplasma gondii*)
6. Live in lymphocytes (*Theileria* spp.)
7. Inactivate host lymphocytes (*Schistosoma mansoni*)
8. Cause polyclonal stimulation of lymphocytes (*Trypanosoma brucei* subspp., *Plasmodium falciparum*, *Babesia microti*, *Entamoeba histolytica*, *Trichinella spiralis*)
9. Activate macrophages (*Leishmania* spp., *Toxoplasma gondii*, *Trichinella spiralis*, *Nippostrongylus brasiliensis*)
10. Shed antigens (*Trypanosoma brucei* subspp., *Entamoeba histolytica*, *Ancylostoma caninum*)
11. Undergo antigenic variation (*Plasmodium falciparum*, *Trypanosoma brucei* subspp.)
12. Inhibit cell or antibody binding (*Schistosoma mansoni*)
13. Suppress immune system (*Trypanosoma cruzi*, *Trypanosoma brucei* subspp., *Leishmania donovani*, *Plasmodium* spp.)

act, there are several possible outcomes: (i) the parasite fails to become established in the host; (ii) the parasite becomes established and kills the host; (iii) the parasite becomes established and the host eliminates the infection; (iv) the parasite becomes established and the host, in trying to eliminate the organism, becomes damaged itself; and (v) the parasite becomes established, and the host begins to overcome the infection but is not totally successful (2). Some representative parasites are presented in this chapter. Obviously, some human parasites have been studied more than others, and these differences are reflected in the amount of available information related to parasite immunology.

Amebiasis

Entamoeba histolytica typically establishes a commensal relationship with the host, and cysts of nonpathogenic trophozoites are excreted, thus perpetuating the life cycle of the parasite (Fig. 32.2). It is estimated that 90% of cases are asymptomatic while 10% of infections progress to symptomatic disease. A small but significant subpopulation of symptomatic individuals develops severe extraintestinal amebiasis, including amebic liver abscess. With the development of axenic culture and antigen purification techniques, *E. histolytica* infections and subsequent host immune responses have been more thoroughly investigated. However, although both humoral and cellular responses occur in amebiasis, the role of immunity is still not completely understood.

Pathogenic *E. histolytica* is now well recognized as a separate species from the morphologically identical but

TABLE 32.10 Immune system antibodies (neutralization, agglutination, complement activation, and facilitated opsonization)

Antibody	General comments	Functionality
IgA	Occurs as 2 subclasses (IgA1 and IgA2); can occur in monomeric, dimeric, or polymeric forms; found in secretions, where it protects the mucous surfaces of the gut, respiratory tract, and urogenital tract; occurs in breast milk	Neutralization of bacterial toxins; inhibition of invasion of the mucosa by agglutinating infectious agents or preventing attachment to the host cell
IgG	Found in serum and extravascular spaces; occurs as 4 subclasses, IgG1, IgG2, IgG3, and IgG4	Most common antibody in secondary immune response; all subclasses can agglutinate microorganisms; IgG1, IgG2, and IgG3 activate complement, with IgG3 being the most effective; IgG1 and IgG4 can cross the placenta; IgG1 and IgG3 can bind to macrophages via their Fc portions
IgM	Found in serum and extravascular spaces; pentameric immunoglobulin; single subclass	First antibody produced in response to antigenic stimulation; agglutinates microorganisms with repeated epitopes; activates complement via classic pathway
IgE	Has an affinity for mast cells, basophils, and eosinophils, to which it binds via the Fc portion	When bound to an antigen, it causes cross-linking, resulting in the release of active substances from the cell to which it is bound

nonpathogenic *E. dispar*. *E. histolytica* uses different virulence factors, including a surface membrane GalNAc lectin that allows adherence and induces cytolysis plus a cysteine protease. Cysteine proteases contribute to tissue invasion, causing degradation of the extracellular matrix, and they participate in the induction of apoptosis (programmed cell death) in cells contacted by the amebae (4). They also assist in circumventing the host immune response through cleavage of secretory IgA and IgG and activation of complement (5). Cysteine proteases are encoded by a number of genes present in *E. histolytica* but not *E. dispar*. A detailed study of cysteine proteases may eventually provide the key to the design of specific inhibitors that could serve as new chemotherapeutic agents. Currently, known amebic virulence factors include the Gal/GalNAc adherence lectin, cysteine proteases, arginase, amebapores, alcohol dehydrogenase, peroxiredoxin, cyclooxygenase 2, and lipopeptidophosphoglycan (6–8). Characterized virulence factors of *E. histolytica* are often down-regulated in nonpathogenic isolates or absent in the nonpathogenic amebic species *E. dispar* and *Entamoeba moshkovskii*.

Humoral Immunity

Coproantibodies can be detected in approximately 80% of patients with amebic dysentery, with a steady decline to about 55% over a period of weeks. During the same time frame, a rise in the level of antibodies in serum can be demonstrated. These data may represent a transient secretory response followed by invasion and penetration of the intestinal mucosa with production of circulating antibody. Once invasive amebiasis has been established, a serologic response can generally be demonstrated within a week after the onset of symptoms. These titers tend to be high and can persist for several years, even after invasive disease has healed or a subclinical infection has been controlled. However, this humoral response during the invasive phase of the disease apparently has little impact on potential reinfections or in the healing process.

IgM is produced, although IgG is found at a higher concentration, with the predominant subclass being IgG2 (9). Data indicate that cleavage of IgG by the extracellular cysteine proteinase of *E. histolytica* trophozoites may limit the effectiveness of the host humoral response (10). The production of anti-ameba IgE is controversial, and its role in *E. histolytica* infections is unclear. A cytotoxic effect on the trophozoites is produced, and organisms lose motility when in contact with serum containing specific antibodies. Also, introduction of antibodies to cultures inhibits growth, and antibody-treated organisms do not induce liver abscess in susceptible animal models.

It is also interesting that sera from healthy individuals with no evidence of past or present amebiasis also have the same effects on organisms as immune sera do. Even after absorption with *E. histolytica* trophozoites, the effects persist, suggesting that they are due to causes other than the presence of natural antibodies. Complement activation is involved, via classic and alternative pathways, and apparently does not require antibodies. Activation of complement pathways results in lysis of the trophozoites. It has been reported that highly virulent strains of *E. histolytica* are more resistant to complement-mediated lysis; thus, complement may also play a role in natural resistance to infection by causing a potential reduction in invasive capacity. However, it is not known if reduced complement activity plays a role in the susceptibility of certain individuals to infection or whether it may be related to host defenses.

Although the data are limited, a suppression of humoral response to sheep erythrocytes in hamsters has been documented when extracts of *E. histolytica* were used.

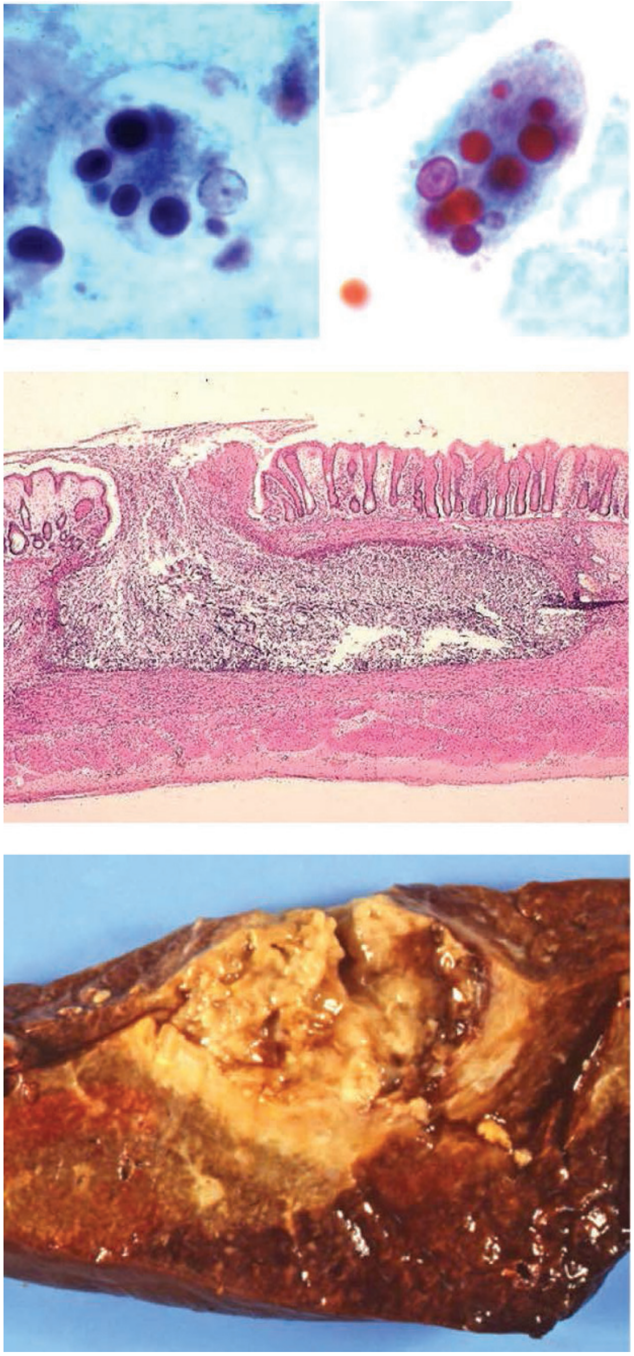

Figure 32.2 *Entamoeba histolytica*, amebiasis. (Top) Two examples of trophozoites containing ingested RBCs within the cytoplasm (morphologic evidence of true pathogen, *E. histolytica*). (Middle) Amebic intestinal "flask-shaped" ulcer. (Bottom) Amebic liver abscess (Armed Forces Institute of Pathology photograph). doi:10.1128/9781555819002.ch32.f2

The effect is enhanced when the erythrocytes and amebic extract are injected on the same day; however, the primary response only is involved. Suppression of the primary response has also been documented with ovalbumin as the antigen.

Survival mechanisms allow the survival of the parasite, often in spite of both natural and immune defenses. One of these mechanisms is capping, i.e., surface redistribution of membrane antigens in amebae, which may circumvent the effect of surface-bound specific antibodies. Antibodies to the amebae bind to the organism and induce a polar redistribution of surface components. The surface becomes an accumulation of folded membranes that extrude as a cap, containing most of the antibodies that were originally bound to the surface. The cap is then released, probably by constriction of a limiting membrane region.

In spite of the production of high levels of antibody in response to an infection with *E. histolytica*, it appears that the humoral response is not protective to the host. This is confirmed by the ease with which reinfection occurs and the fact that high antibody levels can be seen in patients who remain symptomatic with amebiasis.

The identification and structural characterization of three amebic antigens, the serine-rich *E. histolytica* protein (SREHP), the 170-kDa subunit of the Gal/GalNAc-binding lectin, and the 29-kDa cysteine-rich protein, indicate that they all show promise as recombinant antigen-based vaccines to prevent amebiasis (11–14). Recent data confirm that DNA vaccination with SREHP can provide high levels of protection against amebic liver abscess in animal models of disease (15).

Secreted immunoglobulins, defensins, and cathalecidins reinforce mucosal barrier function, actively preventing pathogenic colonization by ameba.

Cellular Immunity

Most research on cell-mediated immunity in amebiasis has been conducted with animal models of amebic liver abscess. However, a number of different approaches to clarify the role of cellular immunity in humans have been taken. One example involved the use of skin test antigens obtained from *E. histolytica* culture. This procedure detects amebiasis long after the patient has recovered from the infection, and it has been useful in epidemiologic studies; patients with invasive amebiasis exhibit a typical delayed-type hypersensitivity reaction, although the reaction is usually negative during the acute phase of an untreated liver abscess (9).

Trophozoites that breach the epithelial barrier elicit a rapid infiltration of neutrophils to the site of infection in early stages of intestinal disease. Intestinal epithelial cells secrete IL-8, a potent neutrophil chemoattractant, when exposed to *E. histolytica*. It is generally accepted that neutrophils are responsible for much of the tissue damage associated with amebic colitis.

Macrophages play important roles in the pathogenesis of both intestinal and hepatic amebiasis. Macrophages are activated by *E. histolytica* trophozoites and are amebicidal when stimulated with IFN-γ, and tumor necrosis factor alpha (TNF-α). The amebic surface component lipopeptidophosphoglycan activates an inflammatory macrophage response upon toll-like receptor 2/6 (TLR2/6) and TLR4 binding. *E. histolytica* DNA also promotes macrophage activation by TLR9 binding. Furthermore, macrophages upregulate TLR2 in response to the amebic galactose-specific lectin. Macrophage amebicidal activity is mediated by nitric oxide (NO) synthase. NO inhibits important amebic virulence factors including the cysteine proteases and alcohol dehydrogenase 2.

Macrophage migration-inhibition assays have shown results similar to those obtained with skin test antigens during invasive disease. Results were negative during the early phases of liver abscesses but became positive after therapy. A number of different animal model studies also confirm that cell-mediated immunity plays an active role in the overall immune response to infection with *E. histolytica* (9).

Concanavalin A-induced lymphocyte transformation with cells from both patients with amebic liver abscess and healthy controls is comparable; similar results have also been demonstrated with phytohemagglutinin. However, studies with infected hamsters indicated reduced reactivity to concanavalin A and phytohemagglutinin; other reports indicate that *E. histolytica* extracts are mitogenic for murine lymphocytes. Induced blastogenesis in lymphocytes from patients with amebic liver abscess has been shown with aqueous *E. histolytica* extracts and a subcellular antigenic fraction, thus indicating *in vivo* sensitization of T lymphocytes to amebic antigens (9).

According to Ortiz-Ortiz (9), all arguments in favor of protective immunity in amebiasis are based on cellular immunity, hence the emphasis on studies involving the *in vitro* interaction of *E. histolytica*, T lymphocytes, and macrophages. A compilation of some of these studies can be seen in Tables 32.11 and 32.12. It is apparent from these studies that cell-mediated immunity limits the clinical manifestations of amebic liver abscess and protects against recurrent infections.

Most studies reinforce the idea that cell-mediated immunity is the most important factor in acquired protective immunity. A number of factors support this conclusion: (i) cellular anergy that supports the initial *E. histolytica* invasion; (ii) increased incidence of invasive amebiasis after T-cell suppression or splenectomy; (iii) protective impact of T-cell stimulants; (iv) after recovery from amebic liver abscess, appearance and persistence of a delayed-type hypersensitivity reaction to amebic antigens; (v) transfer to immunity via sensitized T cells; and (vi) the lysis effect of cytotoxic T cells stimulated with antigen and activated macrophages.

TABLE 32.11 Interaction between *Entamoeba histolytica* and T lymphocytes *in vitro*

Study	Comments
Virulent *E. histolytica* with lymphocytes from patients who have recovered from amebic liver abscess	Parasite lysis (also with lymphocyte supernatant fluids)
E. histolytica with lymphocytes, peritoneal cells, or spleen cells from infected hamsters	Parasite lysis; may have been caused by lymphokine-activated macrophages
Lymphocytes (treated amebic liver abscess patients) with ameba antigen or nonimmune T cells (PHA[a] stimulated)	Parasites killed
E. histolytica with supernatant fluids of stimulated T cells	Inhibition of DNA and protein synthesis; not toxic

[a] PHA, phytohemagglutinin.

Anergy during the course of amebic liver abscess is well documented. Animal models reveal tissue destruction with minimal inflammatory reaction surrounding these abscesses. One explanation for this anergy might be a temporary desensitization caused by circulating antigen; it is not thought to be due to decreased T-cell numbers, since normal levels have been detected in patients with amebic liver abscesses (9).

Phagocytosis by both peripheral blood polymorphonuclear leukocytes and monocytes is reduced in various circumstances related to amebiasis. Phagocytic function in polymorphonuclear leukocytes was more depressed in patients with amebic liver abscess than in patients with other manifestations of *E. histolytica* infection or in healthy controls. In evaluating the functional capacity of monocytes, phagocytosis was significantly depressed in both liver and intestinal amebiasis and bactericidal function was depressed even more in liver amebiasis.

Studies of patients with amebic liver abscess that had been healed for a minimum of 9 weeks indicated that the $CD4^+$ (helper, inducer T-cell) lymphocyte subpopulation was smaller and the $CD8^+$ (suppressor, cytotoxic T-cell) subpopulation was increased, resulting in a lower cell ratio in patients with amebic liver abscess than in controls (16). However, when the same group of patients was checked a year later, four of five demonstrated an increased $CD4^+$ cell percentage and three of five showed an increased ratio of $CD4^+$ to $CD8^+$ cells. Since T lymphocytes from patients cured of amebic liver abscesses have been shown to destroy *E. histolytica* after activation with parasite antigens, this may have an impact on host resistance in these patients.

TABLE 32.12 Interaction between *Entamoeba histolytica* and macrophages *in vitro* and *in vivo*

Study[a]	Comments	Reference(s)
Virulent *E. histolytica* with nonactivated macrophages	Lysis of mammalian cells; no harm to amebae	95
Virulent *E. histolytica* with activated macrophages (lymphokines induced with ameba soluble protein, ConA, or PHA)	Amebae killed; dependent on cell-cell contact, time, and oxidative and nonoxidative processes; decrease in macrophage viability, possibly owing to lysis by *E. histolytica* toxic products	96
Silica poisoning of macrophages or use of antimacrophage serum	Increased susceptibility to amebic liver abscess; larger abscesses; dissemination to other tissues (hamsters, guinea pigs)	96, 97
Bacillus Calmette-Guérin-stimulated macrophages	Decreased susceptibility to amebic liver abscess; smaller abscesses; less dissemination (to hamsters, guinea pigs)	96, 97
Congenitally athymic nude mice (*nu/nu*), macrophage dependent	Resistant to invasive amebiasis; can limit development of liver abscess	98, 99

[a] ConA, concanavalin A; PHA, phytohemagglutinin.

Natural Immunity in Humans

Certain HLA class II alleles and haplotypes are associated with drastically decreased rates of *E. histolytica* infection (8). Conversely, a single amino acid replacement (Q223R) in the extracellular domain of the leptin receptor encoded by a single nucleotide polymorphism is associated with a nearly 4-fold increase in susceptibility to infection by *E. histolytica* as well as an overall decrease in time to infection (8). It is clear that the host genetic background influences susceptibility to amebiasis. Hopefully, the identification of additional host genetic factors will lead to a better understanding of the pathogenesis of amebiasis, along with enhanced therapeutics in these specific populations.

Giardiasis

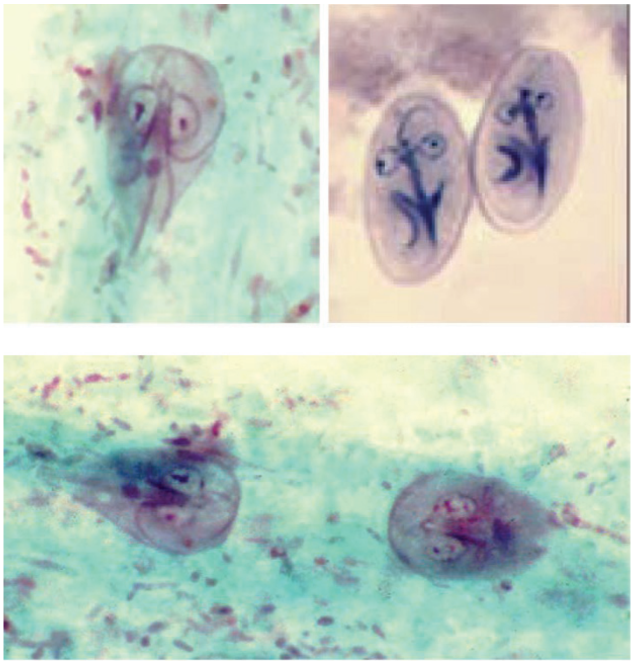
Giardia lamblia is one of the most commonly diagnosed flagellates in the intestinal tract and in many areas of the world (Fig. 32.3). Although various criteria have been used to differentiate species of *Giardia*, there is still disagreement about classification and nomenclature. On the basis of different species names for different animal hosts, there are approximately 50 *Giardia* species. However, there are also data to suggest either biological or antigenic differences among many of these species.

Studies during the last 15 years have confirmed that *Giardia* organisms elicit an immune response that probably plays a role in the variable host response generated to the presence of the parasite. Early data indicating a lower incidence of symptoms in individuals who were repeatedly exposed to the organism suggested the presence of an immune response. Subsequent studies with humans and experimental animals have confirmed the presence of both humoral and cellular immune responses to *Giardia* spp.

In giardiasis a diffuse loss of microvillous brush border, usually combined with villous atrophy, is responsible for malabsorption, which ultimately causes diarrhea. Other mucosal changes include crypt hyperplasia and increased infiltration of intraepithelial lymphocytes. The loss of brush border surface area, reduced disaccharidase activities, and increased crypt/villus ratios are mediated by CD8$^+$ T cells, while both CD8$^+$ and CD4$^+$ small mesenteric lymph node T cells regulate the influx of intraepithelial lymphocytes (17).

Antigenic variation has been documented in giardiasis, and variation at the surface membrane of trophozoites occurs frequently. These antigens are composed of cysteine-rich proteins, and B-cell-dependent mechanisms are probably responsible for the surface antigen switch (18). Apparently, individual organisms express only one variant-specific pro-

Figure 32.3 *Giardia lamblia*, giardiasis. (Upper, left) *Giardia* trophozoite; (right) *Giardia* cysts. (Lower) *Giardia* trophozoites within mucus (fecal specimen).
doi:10.1128/9781555819002.ch32.f3



tein at a time; the detection of multiple surface-labeled bands in some of the studies resulted from subpopulations of trophozoites expressing several different variant surface protein types (19).

Humoral Immunity

The majority of infected patients produce detectable levels of *Giardia*-specific antibodies; however, the biological role played by these antibodies in the host immune response to the infection is unclear. Diagnostic procedures have been developed for the detection of short-lived IgM anti-*Giardia* antibodies and IgG antibodies that may remain at high titers for many months after the patient has been treated and cured. Specific anti-*Giardia* IgM responses in serum were found in 100% of human volunteers experimentally infected with human-source *Giardia* spp. (20). Some studies indicate a correlation between the presence of antibody and symptoms in the patient. Other studies, using different antigens and antibody detection procedures, fail to confirm this correlation.

In asymptomatic patients, the presence of antibody may play a protective role or serve merely as an indicator of infection. Certainly, data indicate that people who are repeatedly exposed to the parasite will tend to be asymptomatic and will have high levels of *Giardia*-specific antibody in serum and breast milk. Patients with hypogammaglobulinemia also have a high rate of diarrhea, often due to *Giardia* spp., and children with chronic diarrhea and giardiasis have an increased incidence of hypogammaglobulinemia. Also, AIDS patients who have giardiasis but no specific antibody also have acute symptomatic infections (21). In contrast to this group of AIDS patients, those who have giardiasis with circulating *Giardia*-specific antibody may have symptoms unrelated to their *Giardia* infection.

Giardia-specific IgA may also be important in both defense against and clearance of the parasite. In one study, patients with symptomatic giardiasis had higher levels of IgA in serum than did uninfected controls and none of the patients were IgA deficient (21). The degree of protection of breast-fed infants against *Giardia* infection also depends on the level of IgA-specific antibodies in breast milk. In the intestine, IgA antibodies may influence the local immune response by inhibiting parasite adherence, tissue invasion, or penetration of the mucosa by parasite antigens (21). IgA anti-*Giardia* antibodies are the most common immunoglobulin type found in acutely ill patients with giardiasis, and they have been detected in persons exposed to a waterborne outbreak in Vermont and villagers in Thailand (21). The jejunal-plasma immune response to *Giardia* involves a decrease in the number of IgA cells and an increase in the number of IgM cells. The large population of antibody-producing plasma cells that are secreting mainly IgA is evidence of the importance of mucosa-associated lymphoid tissue in giardiasis.

Antigenic variation, a mechanism known for many pathogens to evade the humoral immune response of their vertebrate hosts, was shown to occur on the membrane surface of *Giardia* trophozoites both *in vitro* and *in vivo*. Individual *Giardia* trophozoites express only a single species of variant-specific surface protein (VSP) on the surface of the cell membrane at any given time and are subject to replacement by another VSP every 6 to 13 generations of cell growth (22). Using newly established criteria, the total number of recognized VSPs in *Giardia* trophozoites is now refined to 73 (formerly six experimentally identified).

Another protozoan parasite known to possess a single species of variant surface glycoprotein (VSG) covering the cell membrane surface is the African trypanosome *Trypanosoma brucei*. The bloodstream form of the *T. brucei* cell expresses a single species of VSG on the membrane surface at any given time, but this is regularly replaced by another VSG with an estimated frequency of up to 10^{-3} per cell per generation in an apparent effort toward evading the host immune response.

Cellular Immunity

Antibodies to *Giardia* spp. work together with cellular immune mechanisms. Cellular responses to giardiasis occur at the level of the intestinal mucosa, and a number of inflammatory changes may occur during the infection. Histologic changes during giardiasis include infiltration of polymorphonuclear leukocytes into the epithelium and mononuclear leukocytes into the lamina propria, development of shortened villi, loss of the brush border, damage to epithelial cells, and an increase in epithelial cell mitosis (21). In rare cases, giardiasis is associated with changes that mimic celiac sprue and include complete villous atrophy, dense mononuclear cell infiltration, and flattening of the epithelial cells. This accumulation of inflammatory cells in the intestinal mucosal cells of patients with giardiasis suggests that cellular responses play a role in the overall immune response to *Giardia* infection. However, while these histologic findings suggest a cellular immune response, they may also represent a nonspecific inflammatory response stimulated by the presence of an intraluminal infection.

Experimental animal studies provide evidence that T lymphocytes and Peyer's patch helper T lymphocytes play a role in the host immune response. In athymic mice, which are deficient in both T lymphocytes and Peyer's patch helper T lymphocytes, inoculation with *Giardia muris* results in a chronic infection with large numbers of organisms. In contrast, immunocompetent mice clear the parasite and may develop resistance to reinfection.

Several effector mechanisms have been proposed to eradicate *Giardia* infections, including phagocytosis by macrophages; secretion of defensins, NO, and mucins by epithelial cells; and the recruitment and activation of mucosal mast cells (23). In one study, mast cell counts correlated with epithelial permeability and antigen uptake, suggesting a link between development of other immune responses and mast cell recruitment. Reports also indicate that human mononuclear phagocytes are capable of killing *Giardia* organisms and phagocytizing *Giardia* trophozoites (21). Also, gut-associated lymphoid tissue provides the precursor cells that migrate to the mammary gland and become cells capable of secreting the immunoglobulin components of milk. Despite the number of studies on the immunology of giardiasis, the actual effect of antibody or cellular components on the organism itself is unclear. Future studies on defining specific antigens to which the host immune system responds will play a major role in our understanding of this very common infection. For reviews of current information, see references 18 and 21.

Giardia-specific cellular and humoral immune responses have been studied in mouse models. In mice, αβ T-cell receptor-expressing T cells are required to control infection, and diminished CD4 T cells result in chronic infection. Neither a T-helper 1 (Th1) response nor a Th2 response is absolutely required for protection against *Giardia* infection. CD8 T cells seem not to be important for the control of infection in mice but contribute to giardiasis-related intestinal mucosal injury. Important roles have also been shown for mast cells and interleukin (IL) 6, as well as for B-cell antibody production. Human intestinal lymphocytes stimulated by *Giardia* trophozoites demonstrate the importance of IFN-γ, probably secreted by CD4 T cells (24). In summary, data suggest that *Giardia* actively interferes with host innate immunity, resulting in an immune response able to control the infection but lacking strong inflammatory signals.

Toxoplasmosis

Toxoplasma gondii is an obligate intracellular parasitic protozoan that has a wide host range and causes a zoonotic parasitosis called toxoplasmosis (Fig. 32.4). This infection causes significant morbidity. The most effective measures to minimize disease sequelae are prompt diagnosis and treatment and preventing infection. Natural infection usually occurs from direct contact with oocysts or by ingesting undercooked meat containing bradyzoite cysts. The gastrointestinal route appears to be the most common site of infection with *T. gondii*, and, after disruption of the host cells, the organisms invade adjacent cells and are spread throughout the body via the lymphatics and bloodstream. Since the advent of AIDS, the impact of toxoplasmosis as a major opportunistic infection has led to extensive research in the field of immunology. Infection with *T. gondii* stimulates the development of both humoral and cellular immune responses, with the cell-mediated response being the more predominant. Control of *T. gondii* requires the interaction of multiple soluble (i.e., IL-12, IFN-γ) and cellular components (NK cells, dendritic cells, macrophages, and CD4$^+$ and CD8$^+$ T cells) of the host immune system. These immune responses of the host can dramatically affect the course and severity of the infection.

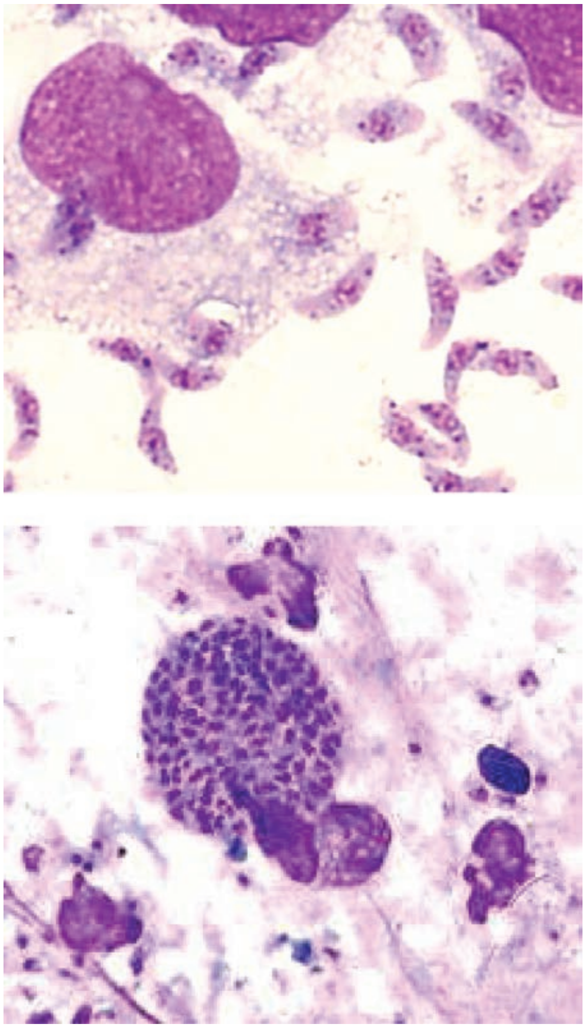


Figure 32.4 *Toxoplasma gondii*, toxoplasmosis. (Upper) *Toxoplasma* tachyzoites (actively proliferating form). (Lower) *Toxoplasma* bradyzoites (resting forms).
doi:10.1128/9781555819002.ch32.f4

Adhesion to the host cell is facilitated by secreted proteins, and invasion uses an actin-myosin-based process. Within the cell, the parasite remains inside the parasitophorous vacuole; the organism prevents the cell from fusing with lysosomes. Eventually the tachyzoites transform into bradyzoites and encyst. Ongoing encystment depends on an ongoing type 1-mediated immune response; IFN-γ and CD4$^+$ and CD8$^+$ cells play a protective role. Although this immune response limits the tissue invasion of the parasite, it also aids the survival of *Toxoplasma* by converting it into a bradyzoite, the resistant form (25).

Humoral Immunity

In spite of the very high antibody titers to *T. gondii* often seen in human infections, humoral antibody plays a secondary role in contributing to protective immunity. The classic approach to the diagnosis of toxoplasmosis has always been based on the detection of immunoglobulins, specifically IgM and IgG. In infected humans, IgM usually appears within 2 weeks after infection, whereas IgG antibodies appear later and their levels peak at approximately 2 months postinfection. The IgG titer decreases gradually to a low level and remains at this level thereafter. For this reason, the presence of IgG demonstrates proof of a prior infection with *T. gondii.* Although detection of IgM has always been considered an indicator of acute infection, the development of more sensitive diagnostic methods means that IgM can now be detected months to years after the initial acute infection. Unfortunately, these findings also complicate the interpretation of serologic test results in patients with toxoplasmosis.

IgA antibodies can be detected early in infection, and their level decreases between 3 and 9 months after infection. The detection of both IgA and IgM at the same time indicates the acute phase of toxoplasmosis and is currently used for risk evaluation of pregnant women. Apparently, IgE antibodies also appear early in infection and then their level begins to decline; the detection of IgE could also serve as an indicator for acute disease. One study indicated the presence of IgE in 86% of infected patients (26). The presence of IgE in immunosuppressed individuals appears to be correlated with the onset of complications such as adenopathies, chorioretinitis, and disease reactivation (27).

Unfortunately, in spite of what is currently known about the humoral response in toxoplasmosis, routine serologic tests are often inadequate for the diagnosis of congenital disease. Specific IgG can persist in a child for months and cannot be differentiated from maternal IgG. However, both IgM and IgA antibodies do not cross the placenta and can be detected in infected fetuses as early as the second trimester of pregnancy, assuming that the mother became infected soon after conception (28). Since children at 1 year of age have only 20% of the level of IgA in adults, early synthesis of specific IgA might also be an indicator of congenital infection (29).

A number of attempts have been made to confer resistance to *T. gondii* by passive transfer of immune homologous or heterologous antisera. The results of these studies have indicated conflicting outcomes; some investigators have reported no protection, whereas others have reported significant protection. The results appear to be related to the choice of experimental host species, specific parasite strains, and transfer of small volumes of high-titer antisera. It appears that anti-*Toxoplasma* antibody can be protective under carefully controlled conditions.

When extracellular tachyzoites are exposed to antibody in the presence of complement *in vitro*, their morphology is altered: the cells become vacuolated and coarse, collapse, and lyse. The changes in dye permeability in the Sabin-Feldman dye test are based on these changes seen with a combination of antibody and complement. However, the *in vivo* intracellular location of the parasite protects it from the circulating antibody.

T. gondii patients have a 2-fold higher level of IL-6 as compared to healthy subjects, which seems to confirm the presence of an inflammatory state. The major function of IL-6 is through the action on B lymphocytes. It is a mediator responsible for the production of acute phase proteins and increased cytotoxic activity of NK cells. IL-6 is an early and sensitive, although nonspecific, marker of inflammatory states.

Also, IL-10 is five times higher in patients with toxoplasmosis than in healthy controls. IL-10 plays an essential role in the inflammatory response during acute *T. gondii* infection, since it inhibits the cellular-type immune response (IL-12, TNF-α) and inflammatory response (IL-6). IL-10 counteracts the harmful effects of the inflammatory response, which is based on the increased production of TNF-α, IFN-γ, and NO associated with intestinal multiplication of *T. gondii*. IL-10 deactivates macrophages, induces γ and facilitates intracellular parasite survival. IL-10 induces immunosuppression during *T. gondii* invasion, which is beneficial both for the host and the parasite (30).

Cellular Immunity

Cellular immunity is the key component of the host's immune reaction to toxoplasmosis. Macrophages, T lymphocytes, and NK cells, as well as the cytokines, are major components of the immune response (21). A number of studies have shown that there is a lower level of lymphocyte transformation in patients with acute disease than in chronically infected patients. In the presence of parasite antigens, lymphocytes from patients with evidence of infection for more than 1 year proliferate, whereas lymphocytes from seronegative patients do not (21).

Animal studies have confirmed the key role of T lymphocytes in protective immunity against *T. gondii.* In infected mice, depletion of CD4$^+$ T lymphocytes reactivates toxoplasmosis in the central nervous system. These cells also play a role in the development of host resistance and in controlling brain cyst development. Apparently, in the mouse model there is a synergistic relationship between

$CD4^+$ and $CD8^+$ T-cell subsets, with $CD4^+$ cells participating in the development of resistance during vaccination or acute infection and $CD8^+$ cells being involved in the maintenance of a protective immune response and the inhibition of cyst formation. $CD4^+$ and $CD8^+$ cells are the key players involved in host resistance in toxoplasmosis. The $CD8^+$ cells are activated by IL-2 secreted by the $CD4^+$ cells, and they exhibit cytotoxic activity against tachyzoites or cells infected with *T. gondii.*

Studies of patients with acute toxoplasmosis have shown a significant elevation in levels of suppressor T cells in patients with symptoms lasting more than 4 weeks. A reversed $CD4^+/CD8^+$ cell ratio is also seen and persists for 2 to 4 months after infection. By using flow cytometry and differential leukocyte counts, an increase in the absolute number of $CD8^+$ T cells was confirmed in patients with symptomatic toxoplasmosis, with no significant change in $CD4^+$ cell levels. Also, cloned $CD4^+$ and $CD8^+$ cells from a symptomatic patient produced less IFN-γ after stimulation with *T. gondii* antigen than did T cells from an asymptomatic patient.

Immunosuppression

Although information continues to expand, it is known that $CD8^+$ cells can be stimulated by *T. gondii* antigen to suppress lymphocyte proliferation; both the suppression and increase in the level of the $CD8^+$ T-cell subset correlate with a more severe and prolonged clinical course (31). This study also supports the suggestion that suppressor T cells play a role in prolonging the symptoms of toxoplasmosis. Lymphadenopathy and elevated numbers of $CD8^+$ T cells have been found in patients with lymphatic toxoplasmosis; the same picture is also seen in patients with viral infections known to cause mononucleosis (Epstein-Barr virus and cytomegalovirus). Overall, the immunosuppressive effect seen in toxoplasmosis is apparently limited to the T-cell responses, while B-cell functions are unaffected.

In congenital infections, T-cell functions are also impaired; studies indicate that most congenitally infected infants demonstrate specific immunologic tolerance to *T. gondii* (32). The presence of the parasite at a critical stage of fetal development results in production of lymphocytes that are unable to distinguish immunologically between parasite and self. It is possible that increased numbers of suppressor T cells that occur during fetal life could induce tolerance by the inhibition of other lymphocytes and production of less IFN-γ and IL-2. Also, in symptomatic babies, these diminished responses to *T. gondii* antigens usually correlate with more severe disease.

In normal, unstimulated macrophages, *T. gondii* tachyzoites can continue to multiply; however, in activated macrophages, vacuoles containing living tachyzoites fuse with lysosomes and the parasites are killed. Both oxygen-dependent and oxygen-independent mechanisms are involved in parasite killing.

There is also evidence to indicate that platelets are cytotoxic for tachyzoites when direct cell-to-cell contact is established, even in the absence of antibody. These findings certainly suggest a role for platelets as one of the mechanisms in host defense against toxoplasmosis.

In two studies, a protective effect of vaccination of mice with a combination of antigen and IL-12 or IL-15 has been demonstrated. In the study using a recombinant surface antigen (rSAG1) plus IL-12, this combination reduced the parasite load in the brain by 40% (33). The second study indicated that the γδ T-cell response to *T. gondii* was enhanced by the administration of exogenous IL-15 in the presence of parasite lysate antigen; the survival times after lethal challenge were lengthened (34). In this study, IgG1 and IgG2a antibody titers were increased, as was splenocyte lymphoproliferation.

African Trypanosomiasis

Human african trypanosomiasis, or sleeping sickness, is a neglected tropical disease of significant public health importance across much of Africa; nagana is the corresponding disease in livestock (94). According to recent data, 50 million people are at risk of contracting trypanosomiasis. In Africa, the extensive distribution of the tsetse fly vector, *Glossinia* sp., has rendered ca. 10^7 km^2 of potential grazing land unavailable for livestock; approximately one-third of the cattle are at risk of trypanosomiasis. Trypanosomiasis manifests in humans as either the acute form, caused by *Trypanosoma brucei rhodesiense*, or the chronic form due to *T. b. gambiense* (Fig. 32.5). In either case, the trypanosomes live in the bloodstream and are directly affected by the production of antibodies by the host.

Humoral Immunity

In reviewing the immune system response of the host to the presence of these parasites, it is important to understand the concept of antigenic variation. It has been long recognized that African sleeping sickness is characterized by a series of parasitemia peaks in the blood. This successive wavelike pattern is due to the appearance of trypanosomes expressing a different antigenic identity. Organisms that have changed their antigenic identity can escape the host immune response and can initiate another increase in the level of parasitemia. The success of this infection depends on the parasite's ability to select between hundreds of genes that encode the variant surface glycoprotein (VSG) or variant surface protein (VSP). Both designations are correct. As the host immune response produces high levels of antibody against one variant, parasites expressing a different VSG gene begin to proliferate. These organisms

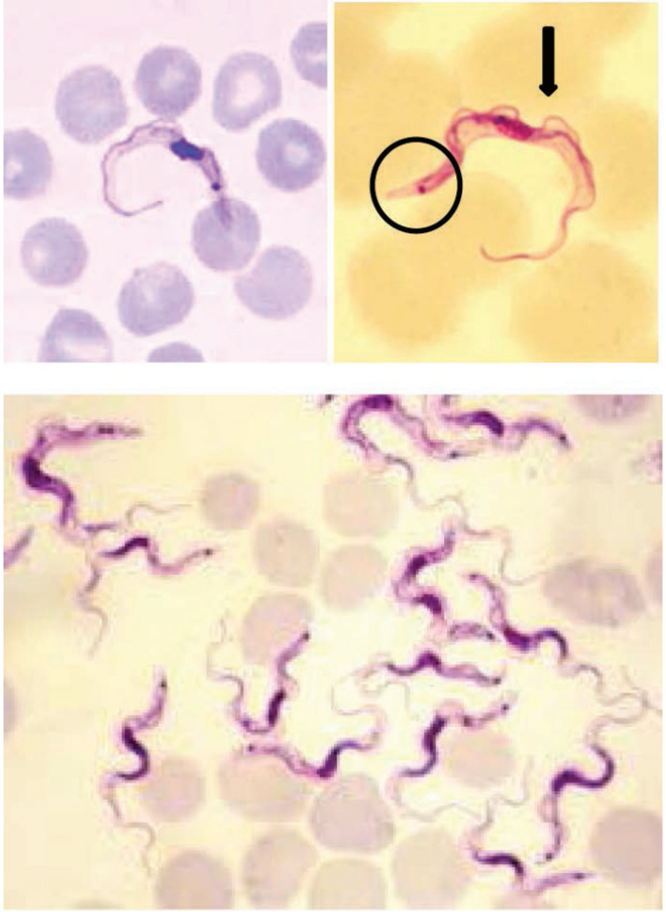

Figure 32.5 *Trypanosoma* sp., African trypanosomiasis. (Upper) *Trypanosoma brucei gambiense*/*T. b. rhodesiense* trypomastigotes in thin blood films; note the very small kinetoplast (circle) and undulating membrane (arrow). (Lower) African trypanosomiasis, heavy parasitemia. doi:10.1128/9781555819002.ch32.f5

persist until they are killed by the immune response, and this pattern is repeated multiple times (35).

We now understand VSG to be a 58-kDa glycophosphatidylinositol-anchored glycoprotein, having predominantly an α-helical secondary structure, with highly variable sequences embedded at the N terminus and monoallelically expressed from a repertoire of hundreds of genes. The factors that induce VSG switching have not been totally defined; however, the presence of host antibodies is not necessary for the changes to occur. The number of variable antigenic types that can occur in any one trypanosome population is quite large (100 or more), and more than 1,000 VSG genes have been detected. There is evidence to indicate that the VSG-specific antibodies represent a mixture of T-dependent and T-independent antibodies directed at different epitopes (36). Unfortunately, although these antibody responses play a role in the successive wavelike growth patterns of the organisms, they do not generate long-lasting immunity.

To be expressed, a particular VSG gene must be located in one of 15 telomeric regions termed "VSG expression sites" (ESs), each of which contains a polycistronic transcription unit that includes ES-associated genes. Only one ES is fully active at a time, so only one VSG gene is transcribed per cell. Although this monoallelic expression is controlled at the transcriptional level, the precise molecular mechanism for this control is not understood (37).

Specific changes in the humoral component of the immune response to trypanosomes include an increase in the cellularity of the spleen and lymph nodes, an increase in the proliferation of spleen cells, an increase in the number of B cells (not T cells), an increase in the IgM level, the appearance of antibodies reacting with nontrypanosome antigens, and the appearance of autoantibodies, rheumatoid factors, and immune complexes (38).

Cellular Immunity

Studies of TNF-α have shown that it is involved in many physiologic functions, and it has been implicated in the pathogenesis of septic shock and systemic inflammatory reactions. Increased levels have been seen in sera from patients with other parasitic infections such as malaria and leishmaniasis; in patients with malaria, increased levels of TNF-α correlate with disease severity. In a recent study, an increase in the level of TNF-α was observed in sera from patients with African trypanosomiasis compared with controls. Patients were classified as being in the early stage (blood, lymphatic) or late stage (meningoencephalitocytic) of the disease. An increase in the level of TNF-α was also noted in late-stage patients compared with those in the early stages of the disease. Data indicated that levels of TNF-α in the serum of patients with African trypanosomiasis were definitely correlated with disease severity (signs of inflammation or presence of major neurologic signs), indicating that TNF-α could be involved in at least some aspects of physiopathology in human African trypanosomiasis (*T. brucei gambiense*) (39).

Immunosuppression

It is also well documented that another key feature of African trypanosomiasis is suppression of the host immune system. Increased incidence of opportunistic infections in patients with African trypanosomiasis is well recognized and has been known since the early 1900s. Both T-cell and B-cell functions can be severely suppressed.

Animal studies have demonstrated two different pathways, one that is suppressor cell dependent and one that is suppressor cell independent. Consequently, suppression has been attributed to polyclonal activation of B cells and to the generation of suppressive cells, two different pathways that are probably coexisting mechanisms.

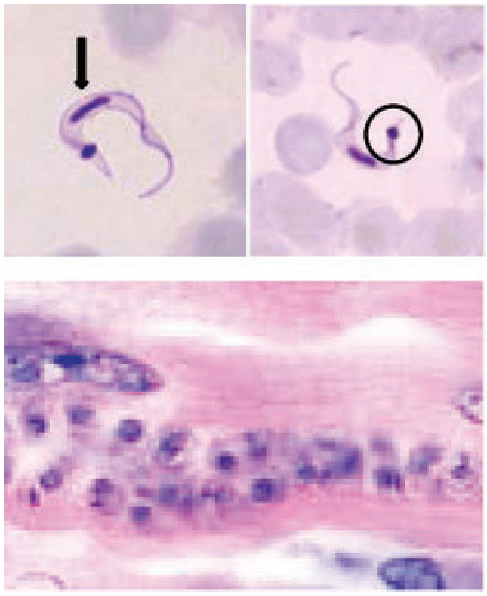
Prostaglandins also play a large role, not only in immunosuppression but also in other areas such as immune system modulation and pathogenesis. It has been shown that prostaglandins in cerebrospinal fluid from patients with sleeping sickness are probably responsible for sleep induction (40).

American Trypanosomiasis

American trypanosomiasis (Chagas' disease) is caused by *Trypanosoma cruzi* and is one of the major health problems in Latin American countries. It is estimated that 100 million persons are at risk of infection, of whom 16 million to 18 million are actually infected, and there are approximately 50,000 deaths per year due to Chagas' disease. In certain areas of endemicity, approximately 10% of all adult deaths are due to Chagas' disease. In addition to humans, numerous species of wild and domestic mammals can harbor the infection and serve as an enormous parasite reservoir.

The parasite has two stages in the host: the amastigote, the intracellular replicating form, and the extracellular trypomastigote, the infective form (Fig. 32.6). Infection by *T. cruzi* induces a complex immune response that involves effectors and regulatory mechanisms. Control of the infection requires a strong humoral and cellular immune response; hence, the outcome of host-parasite interaction in the early stages of infection is extremely important. During this period of the infection the innate immune response is very important and the macrophage's role in this response is vital. After being phagocytized, the parasite is able to develop intracellularly; however, during later periods, these cells induce its elimination by means of toxic metabolites. In turn, as the infection progresses, adaptive immune response mechanisms are triggered through the Th1 and Th2 responses.

Figure 32.6 *Trypanosoma cruzi*, American trypanosomiasis. (Upper) *Trypanosoma cruzi* trypomastigotes in thin blood films. Note the large kinetoplast (circle); the nucleus tends to be somewhat linear (arrow). (Lower) *T. cruzi* amastigotes in muscle. doi:10.1128/9781555819002.ch32.f6



Immune responses to *T. cruzi* are complex and involve many components, both effectors and regulators. Nonspecific immunosuppression occurs during the first stage of the infection, and the ability to adapt and evade this response allows the organism to invade cells and spread. Thus, the parasite may remain indefinitely in the host's tissues since it is not completely eliminated.

Shortly after infection, both humans and animals develop an immune response to the presence of the parasites; this is clearly demonstrated by the development of parasite-specific antibodies and hypersensitivity reactions. As with many other parasite infections, these immune responses do affect the outcome of the infection; however, host protection is limited. Both antibody-mediated and cell-mediated mechanisms are involved. It has also been shown that autoantibodies directed against laminin, tubulin, and nervous tissue are present; however, whether these autoantibodies contribute to disease is somewhat unclear.

Humoral Immunity

Early in the infection, *T. cruzi* induces an intense inflammatory response, which plays a crucial role in pathogenesis. During the initial phase of the infection, IgM is predominant, whereas later, IgG and IgA become the major antibody classes represented. Antigenic variation, which is characteristic of infections with African trypanosomes, is less common in *T. cruzi* infection. In spite of humoral and cellular immunity to *T. cruzi*, the infection is able to persist in the host.

Reviews of serologic test results show that patients can be divided into four categories: (i) uninfected, (ii) indeterminate (seropositive but asymptomatic), (iii) cardiac (symptomatic with palpitations, dyspnea, syncope, and pulmonary embolus, with findings consistent with chagasic cardiomyopathy), and (iv) mega-gastrointestinal (symptomatic with dysphagia, constipation, and abdominal pain, with documented visceromegaly of the esophagus or colon determined by barium or surgical exploration). Individuals with both cardiac and megagastrointestinal disease were categorized as both (41). There were no significant differences in the levels of antitrypanosomal antibodies among the various clinical groups of chronically infected individuals. Titers obtained by hemagglutination, indirect fluorescent-antibody assay, and enzyme-linked immunosorbent assay allowed a clear distinction between seropositive and seronegative individuals.

The use of recombinant *T. cruzi* antigens greatly improves the early diagnosis of congenital Chagas' disease, especially through the detection of IgM. Although detection of IgM has proven to be very helpful, additional studies related to IgA will be justified, particularly since some congenitally infected infants, who do not produce IgM, may develop specific IgA (42).

Glycoinositolphospholipids are some of the major glycolipids of the *T. cruzi* surface that activate B cells. Apparently, *T. cruzi* glycoinositolphospholipids can directly stimulate NK cells and can induce immunoglobulin production in the absence of T cells and NK cells. These studies indicate that this *T. cruzi*-derived molecule may be one of the stimulators that lead to NK cell activation during infection (43).

An adequate production of proinflammatory cytokines such as IFN-γ, TNF-α, IL-1, IL-12, IL-6, and IL-18 is essential for controlling infection by intracellular parasites. Also, IL-17 may regulate the recruitment of inflammatory cells and the differentiation of Th1 in heart tissue. Therefore, in order to resolve the *T. cruzi* infection, a balance is required between the immune response mediated by Th1 and by Th2. Th1 cells are responsible for the production of inflammatory cytokines, while Th2 cells have an anti-inflammatory function and are involved in the antibody-mediated response. IL-12 and IL-18 produced by dendritic cells and macrophages promote the development of Th1 cells that produce IFN-γ, while IL-4 induces the expansion of Th2 cells and of high amounts of IL-10.

Cellular Immunity

Cell-mediated immunity has also been implicated as a cause of the tissue destruction, including cardiomyopathy and megacolon, seen in Chagas' disease. In animal studies, the transfer of lymphocytes from chronically infected mice to uninfected mice can destroy cardiac cells and the T-cell lines can recreate some of the neuropathologic changes seen in chronic disease (41).

Decreased cell-mediated immune responses have been found in symptomatic patients compared with asymptomatic patients. Future work will probably be focused on T-cell suppression factors or selective cell depletion as possible mechanisms for cell-mediated immunity alterations.

$CD8^+$ T cells are critical to the control of *T. cruzi* infection and function in multiple ways, the most important being the production of IFN-γ; IL-12 is also involved in protection against *T. cruzi* (44–46). This cytokine is produced early by NK cells and later by T cells. Cytokine responses in *T. cruzi*-infected children have been partially clarified; the children were 5 to 14 years of age and were from an area of endemic infection in Paraguay. This age group tends to be the most severely affected by the early phases of infection. Acutely infected children showed a distinct Th1-type IFN-γ cytokine response to infection. The cytokine pattern seen in the seropositive, asymptomatic group was the Th0 type (expression of both IFN-γ and IL-4). It was suggested that selective induction of a Th0-type cytokine pattern is important for the development of cell-mediated and humoral responses that suppress the parasite burden, thus prolonging the onset or limiting the disease severity of chronic Chagas' disease years later (47). Also, the frequency of IFN-γ-producing T cells in patients with chronic Chagas' disease seems to be associated with a history of recent exposure and with the clinical status of the patient (48).

Reduced production of IFN-γ by $CD8^+$ T cells is associated with increased severity of Chagas' disease in humans. In chronic infection, $CD8^+$ T cells serve as effector memory cells, undergo rapid expansion, and demonstrate effector functions following reexposure to antigen. However, these responses appear to develop relatively slowly, and the effector function of the $CD8^+$ cells is compromised in some tissues, including muscle (45).

In several patients coinfected with *T. cruzi* and HIV with high parasitemia, no clinical or parasitological evidence of *T. cruzi* reactivation was seen. $CD4^+$ T-cell counts decreased over time in two patients, and the lymphocyte proliferative response to the parasite was very low in all patients. Thus, *T. cruzi* infection appears to have a long silent course in immunocompromised HIV-infected patients (49).

In a group of 23 patients with AIDS and *T. cruzi* infection, 20 patients developed severe multifocal or diffuse meningoencephalitis with necrosis and hemorrhage associated with numerous tissue parasites (50). The second most severely affected site was the heart, with myocarditis in 7 of the 23 patients. Both acute myocarditis and meningoencephalitis are thought to be caused by relapses of chronic *T. cruzi* infection, but this hypothesis is not universally accepted. Since immunologic defense against *T. cruzi* is mediated mainly by T lymphocytes and since the $CD4^+$ population of T cells is depleted in AIDS patients, it appears in certain circumstances that AIDS may be responsible for reactivation of *T. cruzi* infections. In patients who do not have AIDS but have fatal, acute infections with *T. cruzi*, meningoencephalitis is uncommon and is seen most often in children younger than 4 years. Cases of Chagas' disease in immunosuppressed individuals have been described as having pseudotumoral presentations. There are expanding mass lesions in the cranial cavity, causing intracranial hypertension, and they mimic various neoplasms such as gliomas, lymphomas, or metastases (50). The United States, with the largest HIV-infected population reported by the

World Health Organization (WHO) up to 1987, is also known to have a significant number of individuals with Chagas' disease (51).

Studies of IL-12 indicate that this cytokine can act as a more selective amplifier of *T. cruzi* reactive cells than IL-2 does. By enhancing parasite antigen-specific immunity, IL-12 could be potentially therapeutic, with the ability to control reactivated *T. cruzi* infections associated with AIDS or other immunosuppressive conditions (52).

Macrophages play an indispensable role in the primary response to pathogens but also take part in the resolution process of the inflammation and homeostasis of tissues. These cells are activated by IFN-γ and TNF-α (type 1), or by an alternative way stimulated by IL-4 and IL-13 (type 2) (53). Classically activated macrophages are currently grouped in group M1, alternatively activated ones are in M2a, those that polarize towards a Th2 response are designated M2b, and those whose stimulation is mediated by glucocorticoids and transforming growth factor β (TGF-β) are placed in group M2c.

Immunosuppression

Suppressed delayed-type hypersensitivity has been reported to occur during acute Chagas' disease. *T. cruzi* also exerts a direct suppressive effect on human lymphocytes. Abnormalities in activated human lymphocytes may be involved in immunosuppression. These changes occur regardless of whether the parasites and cells are in physical contact. There is also evidence that a soluble *T. cruzi* product mediates the suppressive effects. This trypanosomal immunosuppressive factor is a protein and can be purified from sera from chronic chagasic patients but not healthy individuals (48).

B cells isolated at the acute stage of infection have shown marked impairment in their response to polyclonal activators *in vitro*. Studies suggest that B-cell apoptosis and cell cycle arrest could be the mechanisms that control intense B-cell expansion but at the same time could be delaying the emergence of a specific immune response to *T. cruzi* (54).

Splenomegaly, lymphadenopathy, depression of immune system responses to unrelated antigens, hypergammaglobulinemia, and autoimmunity are all indications of immune system physiopathologic changes in Chagas' disease. Minoprio et al. (55) also think that specific antigenic challenges could elicit "nonspecific" immune responses greater than the antigen-specific components of the response. Underlying mechanisms might include, for example, the production of cytokines, the nonspecific "stickiness" of antigens to lymphocyte surfaces, the expression of major histocompatibility complex and other cell surface components (probably IFN-γ and IL-4), and the nonspecific lymphocyte mitogens released by *T. cruzi* or superantigens which could bind to T-cell receptors and trigger accessory cell-dependent T-cell activation.

Studies have shown that there appears to be no correlation between NK and lymphokine-activated killer (LAK) cell functions in the same individual. Neither NK nor LAK cell functions seem to be involved in the immunosuppression associated with chronic Chagas' disease (56).

Autoimmunity

Chagas' disease cardiomyopathy (CCC) is one of the few examples of postinfectious autoimmunity, where *T. cruzi* triggers molecular mimicry-related target organ immune damage. Heart tissue destruction in CCC may be caused by autoimmune recognition of heart tissue by a mononuclear cell infiltrate, often many years after the initial infection. Indirect evidence indicates that there may be cross-reactivity between *T. cruzi* and cardiac tissue. There is also evidence for immune system recognition of cardiac myosin in CCC; the presence of an anti-cardiac myosin cross-reactive *T. cruzi* antigen is suspected as the cause. Studies demonstrate sequence homology to a recombinant *T. cruzi* protein (B13) in several positions of cardiac myosin heavy chain. This recognition of a heart-specific *T. cruzi* cross-reactive epitope in close association with the presence of chronic heart lesions suggests the involvement of cross-reactivity between cardiac myosin and B13 in the pathogenesis of CCC (57, 58). It has been proposed that phagocytic removal of infected apoptotic cardiomyocytes, combined with signaling through innate immune receptors, may be required to initiate immune responses that damage the heart (59).

Studies demonstrate the presence of antibody to myelin basic protein in the serum of mice chronically infected with *T. cruzi.* Studies of the overlapping peptides from the myelin basic protein identified two regions responsible for the cross-reactivity with *T. cruzi* (60). This may provide further evidence to help explain why chronic Chagas' disease is characterized by inflammatory infiltrates in myocardial and nervous tissues, with virtually no demonstrable parasites.

Another study suggests that fraction IV *T. cruzi* (parasite antigen acidic fraction) and sciatic nerve components have some epitopes, possibly carbohydrate, in common. Thus, infection in patients with Chagas' disease could override tolerance to self components and lead to autoimmunity (61). The observation of potentially shared epitopes between some of the parasite and cardiac proteins has led to the popular idea of cross-reactive proteins to explain autoimmunity. Notably, the B13 epitope of *T. cruzi* has been reported to share peptide sequence with cardiac myosin (62).

The scarcity of parasites in the chronic phase of the disease contrasts with the severe cardiac pathology seen in approximately 30% of chronically infected patients. Antigen-specific and non-antigen-specific mechanisms have been suggested to explain T- and B-cell activation leading to autoimmunity. However, the issue of autoimmunity versus parasite persistence as the cause of Chagas' disease pathology continues to be hotly debated. Autoimmune and *T. cruzi*-specific innate or adaptive responses are not incompatible or mutually exclusive, and it is likely that a combination of both is involved in the pathogenesis of chronic Chagas' disease cardiomyopathy.

Malaria

Human malaria is caused by infection with any of five species of *Plasmodium*, with *Plasmodium falciparum* and *Plasmodium knowlesi* being the most pathogenic. The other three species are *P. vivax*, *P. ovale*, and *P. malariae* (Fig. 32.7). Symptoms of malaria infection include fever and malaise; infections with *P. falciparum* or *P. knowlesi* can be fatal. This is particularly true in untreated, nonimmune individuals. Despite the high fatality rate in nonimmune or partially immune individuals, people who live in areas of endemic infection for long periods generally acquire immunity and may be asymptomatic or have very mild symptoms. Why and how this slow development of immunity occurs is not completely understood, particularly when reviewing the very complex life cycle of these organisms.

The vector for malaria is the female anopheline mosquito. When the vector takes a blood meal, sporozoites contained in its salivary glands are discharged into the puncture wound. A surface protein, the circumsporozoite protein, in combination with thrombospondin-related adhesive protein allows recognition of glycosoaminoglycans in the liver, thus providing the targeting mechanism that allows the *Plasmodium* sporozoite to reach the correct liver cells. Within an hour, these infective stages are then carried via the blood to the liver, where they penetrate parenchymal cells and begin to grow, thus initiating the pre-erythrocytic or primary exoerythrocytic cycle. The sporozoites become round or oval and begin dividing repeatedly, resulting in large numbers of exoerythrocytic merozoites that leave the liver and invade the red blood cells (RBCs) (erythrocytic cycle). In *P. vivax* and *P. ovale*, a secondary or dormant schizogony may occur from organisms that remain quiescent in the liver until a later time (hypnozoites). Merozoite surface proteins facilitate recognition of and adhesion to the RBC.

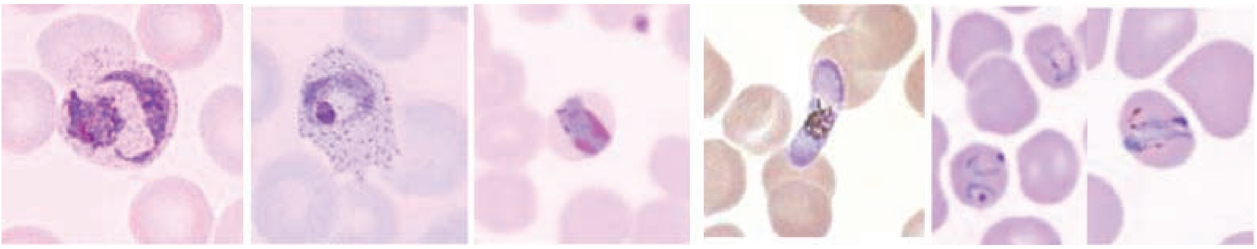
The situation in which the RBC infection is not eliminated by the immune system or by therapy and the number of RBCs begins to increase again with subsequent clinical symptoms is called a recrudescence. All species may have a recrudescence. The situation in which the erythrocytic infection is eliminated and a relapse occurs because of a new invasion of the RBCs from liver merozoites is called a recurrence or true relapse and theoretically occurs only in *P. vivax* and *P. ovale* infections.

Once the erythrocytes and reticulocytes have been invaded, the parasites grow and feed on hemoglobin. As the nucleus begins to divide, the trophozoite is called a developing schizont. The mature schizont contains merozoites, whose number depends on the species, which are released into the bloodstream and invade RBCs, in which a new cycle of erythrocytic schizogony begins. After several erythrocytic generations, some of the merozoites begin to develop into the male and female gametocytes.

The asexual and sexual forms just described circulate in the bloodstream in infections with four species of *Plasmodium*. However, in *P. falciparum* infections, as the parasite continues to grow, the RBC membrane becomes sticky and the cells tend to adhere to the endothelial lining of the capillaries of the internal organs. Thus, only the ring forms and the gametocytes (occasionally mature schizonts) normally appear in the peripheral blood.

If gametocytes are ingested when the mosquito takes a blood meal, they mature into gametes while in the mosquito gut. The male microgametes undergo nuclear division (exflagellation), in which they break out of the RBC, become motile, and penetrate the female macrogamete; the fertilized stage is then called the zygote. The zygote becomes elongate and motile and is called the ookinete; it

Figure 32.7 *Plasmodium* spp., malaria, representative typical stages for each of the five human species. (Left to right) *P. vivax* developing trophozoite in enlarged RBC; *P. ovale* developing trophozoite with RBC fimbriated edges; *P. malariae* band form in normal/small RBC; *P. falciparum* crescent-shaped gametocyte; *P. knowlesi* double rings/band form, resembles mix of *P. falciparum* and *P. malariae*. doi:10.1128/9781555819002.ch32.f7



migrates to the mosquito midgut, secretes a thin wall, and grows into the oocyst, which extends into the insect's hemocele. Within a few days to 2 weeks, the oocyst matures and hundreds of sporozoites are formed. When the oocyst ruptures, the sporozoites are released into the hemocele and dispersed throughout the body, and some make their way into the salivary glands. When the mosquito next takes a blood meal, the sporozoites are injected with saliva into the host.

Each phase of the life cycle is associated with the expression of many stage- and species-specific proteins, many of which are found within the surface membrane of the parasite. These surface proteins are highly polymorphic and antigenically variable. Two hypotheses have been developed to explain the slow development of immunity: (i) immunity is strain specific, and so the individual would not become immune until exposed to all the major antigenic variants circulating within the area of endemicity, and (ii) acute malaria causes extreme immunosuppression, which delays the development of protective immunity. Also, antidisease immunity may be very different from antiparasite immunity. Even continuous exposure to malaria parasites rarely produces sterile immunity, and blood-stage parasites can be detected by PCR in all age groups (63). The wide range of malarial surface antigens helps explain why the development of clinical immunity requires years of repeated infections. Two mechanisms contribute to antigenic diversity, one being the genetic nucleotide replacement and recombination and the second being antigenic variation. Since different antigens are expressed during various parts of the life cycle, naturally acquired immunity tends to be stage specific. Both humoral and cellular components are required for naturally acquired immunity. CD4$^+$ and CD8$^+$ T cells are effective against intracellular liver-stage organisms, while antibodies may interfere with host cell invasion by sporozoites and merozoites. Also, antibodies to variant surface antigens expressed on the RBC surface may facilitate phagocytosis of the infected cells and prevent their adhesion to endothelial receptors.

Apparently, internal antigens are less variable and are partially conserved among different malarial species. When released during the rupture of mature schizonts, these internal antigens appear to stimulate the cytokine cascade, which leads to various symptoms and pathologic changes (64–70) (Table 32.13).

Humoral Immunity

Malarial infection leads to production of high levels of TNF and other proinflammatory cytokines; other findings include elevated immunoglobulin production, activation of complement, and redistribution of lymphocytes from the peripheral circulation to the spleen and other organs. Antibodies can confer protection against *P. falciparum* and *P. vivax*; neonates and infants are protected by maternal antibodies and, in clinical treatment trials, by immune serum or purified immunoglobulins. Animal studies involving passive transfer of whole serum or purified IgG can have a dramatic impact on the erythrocytic cycle by extending the prepatent period, reducing the parasitemia, and leading to spontaneous cure.

Levels of antimalarial antibodies in humans increase during childhood, become maximal during early adulthood, and subsequently remain fairly constant. However, there appears to be little correlation between antibody levels and protection against infection or clinical disease. Also, some of the antibodies are not directed against *Plasmodium* organisms. These antibodies may represent the degree of past exposure rather than functional immunity.

CD4$^+$ T cells are the major source of both IFN-γ and TNF-α, which are implicated in both protection and pathology of this disease. It may be that antibodies and CD4$^+$ T cells provide protection against symptomatic malaria but CD8$^+$ T cells are required for sterile immunity (71).

Cellular Immunity

Animal studies indicate that T-cell-dependent immune mechanisms are required for the development of effective immunity. Although animal model results vary and may not always mimic human immune responses, it does appear that the human antimalarial response is both T-cell dependent and independent. It appears that intrahepatic CD8 T central memory cells, which are maintained in part by liver stage Ag depot and by IL-15-mediated survival and homeostatic proliferation, form a reservoir of cells ready for conscription to CD8 T effector/effector memory cells needed to prevent reinfections (72).

In the erythrocytic portion of the parasite life cycle, T cells are thought to serve at least two functions in immunity: (i) assisting in antibody production and (ii) producing cytokines. The role of cytokines in malaria is very complex; they affect parasite growth and clearance, and they activate macrophages to engulf infected RBCs and to kill the malarial parasites. Elevated concentrations of TNF, IL-6, and soluble TNF receptors have been found in serum in patients with severe *P. falciparum* infections.

TNF induces nitric oxide (NO) production. NO definitely plays protective roles in malaria: (i) it acts as a relaxing factor; (ii) it can downregulate cell adhesion molecules; (iii) it can reduce leukocyte-endothelial cell adherence; (iv) it can scavenge free oxygen radicals; (v) its inhibition can cause endothelial cell alterations, such as albumin leakage and platelet deposition; and (vi) it can reduce platelet aggregation and adhesion to endothelium (73). The role of NO in pathogenesis is somewhat less clear. It is possible

TABLE 32.13 Updated information on immune responses seen in malaria infections[a]

Immune response	Comments	Reference
Parasite antigen-specific IL-10 and antibody responses predict accelerated parasite clearance in *P. falciparum* malaria	Parasite antigen-specific IL-10-mediated antibody responses may play a role in the control of asexual-stage parasite multiplication	64
P. falciparum merozoite surface protein 1 antigen (MSP119): induction of small T-cell response (IL-4), significantly increased by addition of IL-2; if IFN-γ, IL-12, or neutralizing anti-IL-4 antibody is present, T-cell responses are abolished	Recombinant MSP119 is a leading malaria vaccine candidate, can prime nonimmune human lymphocytes	65
Correlation of T-cell response and lymphokine profile with RESA peptides of *P. falciparum* containing a universal T-cell epitope and an immunopotentiator, polytuftsin	Cytokine profile is suggestive of a $CD4^+$ Th1 type of immune response; ideal for killing intracellular pathogens like plasmodia	66
TNF-α, IL-1β, IL-6 implicated in pathogenesis of severe *P. falciparum* malaria; exogenous IL-10 inhibited malarial antigen-induced cytokine production; maximal inhibition when IL-10 used in first 2 h of stimulation of PBMC	TNF-α, IL-1β, IL-6 produced within 2–4 h of stimulation; IL-10 produced after 8 h; findings suggest that IL-10 counterregulates proinflammatory response to *P. falciparum;* severe falciparum malaria may be associated with inadequate negative feedback response by IL-10	67
IFN-γ responses associated with resistance to reinfection with *P. falciparum* in young African children	Differences in Th1/Th2 cytokine balance may be linked to ability to control parasite multiplication, helping explain marked differences in both susceptibility to infection and clinical presentation	68
PfEMP-1 molecule expressed on surface of RBC infected with trophozoite or early gametocyte parasites; IgG antibodies to PfEMP-1 increased with age, mirroring decline in both prevalence and density of asexual stages and gametocytes in RBCs	Immunity to PfEMP-1 may influence malaria transmission by regulation of gametocyte production; mechanisms may be (i) controlling asexual proliferation and density and (ii) affecting gametocyte maturation	69
Cell-mediated immunity and cytokines involved in pathogenesis of malaria; MM and CM cases in children monitored	Both groups (MM, CM) had significantly higher levels of IL-6, IL-10, and TNF-α than did controls; 24 h after admission, IL-10 and IL-6 levels much higher in CM patients; findings suggest activation of monocyte-macrophage system during early stage of clinical malaria	70

[a] CM, cerebral *P. falciparum* malaria; MM, mild *P. falciparum* malaria; PBMC, peripheral blood mononuclear cells; PfEMP-1, *P. falciparum* erythrocyte membrane protein 1; RESA, ring-infected erythrocyte surface antigen.

that NO can mediate early changes in cerebral malaria, such as neurotransmission disturbances, but NO is probably not involved in the actual process of neurovascular damage.

Studies suggest that a systemic, excessive production of TNF, not compensated for by TNF receptors or a hyperproduction affecting vulnerable sites such as the brain, may exacerbate the disease and lead to vascular abnormalities and life-threatening malaria. On the other hand, TNF produced within the context of a specific immune response may be the major protective cytokine in malaria infections. This demonstrates the dual role of this particular cytokine (74).

Although many of the published research reports indicate that a number of monokines and lymphokines are released during acute malaria infections, interpretation of the relevance of cytokine levels may be somewhat misleading (75). Summary information related to the elimination of infected RBCs and mechanisms by which the parasite evades the host immune system can be seen in Table 32.14 (76, 77).

Immunosuppression

It has been well documented that acute malaria infections lead to a decrease in host immune system functionality. These patients have been described as being temporarily immunosuppressed. Direct evidence for this decreased immune system capability has been summarized by Riley et al. (78) and includes increased susceptibility to bacterial infections, reactivation of latent viral infections, and diminished response to some vaccines in children. Indirect evidence is that children protected by chemoprophylaxis for malaria are less susceptible to other infections and tend to respond better to routine vaccinations (78). Although this evidence indicates a lowered immunocompetency level in patients with malaria, it is not known exactly which factors influence this change. It may result directly from the level of parasitemia or from the overall impact of a febrile illness, such as malaria.

During acute malaria infections, there is a decrease in the response to parasite antigens. This may be due to immunosuppression, discussed above, or may just indicate a lack of "priming of the system" in patients with no prior exposure

TABLE 32.14 Mechanisms of infected RBC elimination and evasion of the host immune system in *P. falciparum* infections[a]

Mechanism	Occurrence in *P. falciparum* infection
Infected RBC elimination	
Opsonization	Yes
Antibody-dependent cell-mediated toxicity	Yes
NK cell activity	Yes
Cytotoxic T-cell activity	No
Evasion of host immune system	
Infected RBC knob-like membrane changes	Yes
Infected RBC surface antigenic changes	
Modified host antigens	Yes
Parasite-derived antigens	Yes
Clonal antigenic variation	Yes
Cytoadherence	
Endothelial	Yes
Autoagglutination	Yes
Rosetting of both infected and normal RBCs	Yes
Upregulation of host ligands	Yes

[a] Data from references 76 and 77.

to the organism. Therefore, increased immune responses after cure may be due to decreased immunosuppression or increased levels of preexisting immune responses. Overall, the literature suggests that in some settings T regulatory cells might modulate detrimental inflammation involved in disease induction, while in other cases T regulatory cell-mediated inhibition of immune responses results in increased parasite density, which is also known to be a key determinant of disease severity (79).

Several factors have been described as virulence factors with *P. falciparum*; however, formal documentation that these characteristics are always associated with virulence and significantly more likely to cause severe disease is not abundant (77). These factors include the following: (i) the multiplication capacity in which the biomass of parasites may outstrip host defense mechanisms; (ii) the RBC selectivity limiting the overall number of infected RBCs (however, this is not a big factor for *P. falciparum*); (iii) the cytoadherence and rosetting ability where all five species can cause rosetting but only *P. falciparum* can cause cytoadherence, which is thought to be linked to cerebral malaria; (iv) the potential to release cytokines; (v) antigenicity (those not recognized by the host will have an advantage); and (vi) antimalarial drug resistance, with a great deal of selective pressure against drug-sensitive parasites (77).

Numerous studies seem to emphasize that the host immune system has difficulty in controlling the infection; many unusual host responses have been described. These unusual responses may be due to host immune system overreaction, leading to inappropriate responses. The difference between protective immunity and pathology is a very delicate balance and one in which specific mechanisms are difficult to clarify (80). Specific immunopathologic complications of malaria infection are listed in Table 32.15 (81–86).

Malaria Vaccines

Pre-Erythrocytic and Erythrocytic Vaccines. With a continuing lack of a highly effective vaccine candidate against *P. falciparum* malaria, it remains imperative that all options be explored that could lead to the successful development of such candidates. The development of a subunit vaccine targeting the asexual blood stage of *P. falciparum* malaria infection has been problematic, with only limited success in clinical trials. However, only a fraction of potential blood-stage vaccine antigens have been evaluated as targets, and a number of new promising candidate antigen formulations and delivery platforms are approaching clinical development. There are two main targets of these studies: (i) antigens that are associated with the merozoite's surface or its organelles (pre-erythrocytic antigens), and (ii) proteins that the intracellular parasite exports to the surface of the infected RBC. However, because merozoites are free in the circulation for minutes only, this defines important requirements for the functional quantity and quality of antibodies required for parasite elimination. On the other hand, *P. falciparum* exports between 200 and 400 proteins through the parasitophorous vacuole membrane into the RBC, and some are localized on the RBC plasma membrane. There is also evidence that other gene products such as rifins, stevors, and surfins are also present on the RBC membrane; however, their functional roles are not clearly defined. Major limitations on the development of a merozoite vaccine include the antigenic polymorphism of important targets and problems in producing these molecules in a native configuration. In addition, only a few potential vaccine targets have been investigated, and there is a lack of *in vitro* assays that correlate with immunity *in vivo* and a limited understanding of the types of immunity required. There remain very good reasons to pursue development of vaccines targeting the blood stages, including (i) naturally acquired immunity arises against the blood stages, (ii) an effective blood-stage vaccine could reduce disease severity and mortality, and (iii) this type of vaccine could potentially reduce malaria transmission by reducing gametocyte densities (Table 32.16) (87, 88).

Sexual Stage/Transmission-Blocking Vaccines. Transmission-blocking vaccines, which target the sexual stages of malaria parasites to interfere with and/or block the parasite's development within mosquitoes, have been regarded

TABLE 32.15 Immunopathological complications of malaria infection[a]

Pathology	Suspected mechanism	Comments
Hypergammaglobulinemia	Antigen-induced cytokine production (IL-6); antigenic variation; polyclonal activation	IL-6 from fibroblasts, macrophages, and tumor cells; increases synthesis and secretions of immunoglobulins by B cells; most antibodies not directed against malaria antigens; common feature of antigenic variation is presence of successive peaks of infection, each new peak being antigenically different from the previous one; partial loss of suppressor mechanisms coupled with normal CD4 helper/inducer activity may result in high levels of immunoglobulin in serum (characteristic of people living in areas of endemic malarial infection)
Immunosuppression	Macrophage dysfunction; antigenic competition; structural disruption of germinal centers; disruption of spleen function; polyclonal activation and immune system "exhaustion"	May be due to suppressive effect of malarial pigment ingested; defects in monocyte and neutrophil chemotaxis, reduced monocyte phagocytic function
Nephrotic syndrome	Immune complex deposition; autoimmunity	In nephrotic syndrome associated with *P. malariae,* malaria antigen and immune complexes can be eluted from the kidneys
Autoimmunity	Autoantibodies; antierythrocyte antibodies; dyserythropoiesis; excessive erythrophagocytosis	Defective IL-12 production in early course of infection may result in fatal anemia; destruction of uninfected RBCs occurs through phagocytosis of RBCs bound to merozoites killed as a result of malaria paroxysms (thus, dyserythropoiesis may play a minimal role in anemia); hemolysis is prime cause of anemia, although destruction of parasitized RBCs is not the sole cause of the hemolytic process; bone marrow suppression may be insignificant, but preexisting iron deficiency aggravates the severity of anemia; immune recognition of "self" or "modified self" RBC antigens by B or T lymphocytes may occur
Thrombocytopenia	Excessive removal of platelets; coating of platelets with malaria antigen	May also be due to platelet inactivation; increased platelet turnover; platelet-bound antibody controversial
Hyperactive malarial splenomegaly	Genetic predisposition; hypergammaglobulinemia; chronic increase of lymphocyte proliferation	Associated with increased capacity to clear RBCs by Fc receptor-mediated mechanisms and recognition of reduced deformability; spleen may also modulate cytoadherence
Burkitt's lymphoma	Coendemicity with EBV; polyclonal activation; antigen-induced cytokine production	In patients with *P. falciparum* malaria, loss of cytotoxic T-cell control of EBV in B cells, possibly due to destruction or dysfunction of a subset of CD4 cells responsible for induction of suppressor/cytotoxic CD8 cells, leads to activation and proliferation of foci of B cells containing EBV; the expanded pool and rapid turnover of these cells may increase the chances of malignant transformation, leading to the genesis of Burkitt's tumor

[a]Adapted from references 81–86. EBV, Epstein-Barr virus.

as important targets for disrupting the malaria transmission cycle. Transmission-blocking vaccines provide a promising strategy for controlling *P. vivax*, since this parasite has a unique biological characteristic in which it undergoes early gametocytogenesis prior to the manifestation of clinical symptoms, which enables parasite transmission prior to treatment (89). A proposed target profile for a malaria sexual stage and mosquito transmission-blocking vaccine can be seen in Table 32.17 (90).

A set of conserved "invasion receptors" in the midgut of diverse anopheline species are used by *Plasmodium* ookinetes to attach to the midgut epithelium. Antibodies directed against such receptors have been shown to block development of oocysts in membrane-feeding transmission-blocking assays. A vaccine based on such conserved vector antigens should be effective against all species of *Plasmodium* and would eliminate the need to develop separate vaccines for different *Plasmodium* species. Moreover, since such vaccines target vector antigens, parasite strain diversity, which has been a major problem for malaria vaccine development, will be overcome.

Other factors related to gametocytes will need to be considered. First, the gametocyte reservoir is much larger than suggested by blood film examination, and transmission can occur from individuals with very low numbers of gametocytes. Gametocyte infectivity is related to gametocyte density; however, small numbers of infectious gametocytes in adults are as important in maintaining transmission as larger numbers of gametocytes in children susceptible to clinical attacks of malaria.

TABLE 32.16 *Plasmodium* vaccine development: continuing problems[a]

Problem	Comments
Baseline studies	Detailed studies required: burden of disease, clinical spectrum, incidence of severe malaria and mortality; relapse patterns, strain heterogeneity, interactions with other species; mixed infections; economic analyses
Polymorphisms	The existence of many polymorphisms in antigens selected for vaccine development requires new immunologic strategies for eliciting cross-reactive immune responses. Another option would be the design of large constructs consisting of multiple alleles of variant antigens.
Antibody titers	Need for extremely high antibody titers for anti-merozoite antigen vaccines to achieve protection
Protective immune responses	Knowledge is limited regarding the full range of protective immune responses to the parasite developmental stages. Need to clarify possible effector roles for $CD4^+$ T cells against pre-erythrocytic and erythrocytic antigens
Consensus	Lack of consensus regarding mechanisms of blood-stage immunity and vaccine design (e.g., antibody versus T cell-inducing)
Adjuvants	Lack of safe, well-defined adjuvants
Potential vaccine candidates	Less than 1% of parasite genes have been explored in the context of vaccine candidates from all parasite developmental stages.
Screening methods	Lack of reliable screening methods for selection of promising vaccine candidates
Recombinant expression systems	Need for recombinant expression systems capable of producing plasmodial proteins like that found in the native parasite molecule. Need comprehensive structural studies to define native antigen structures.
P. vivax vaccine	Very limited attention to vaccine development for *P. vivax*, the cause of significant worldwide morbidity. Potential problems include: • Gametocytes appear early in the infection • Persisting hypnozoites in the liver • Extrinsic cycle is shorter, completed at lower temperature • Efficient transmission even when mosquitoes are highly seasonal • *P. vivax* and *P. falciparum* exist in same geographic area • Data on sensitivity to drugs, especially primaquine (issues of primaquine tolerance and resistance), rate of G6PD deficiency.

[a] Adapted from references 3, 87, and 88.

Helminth Infections

Helminths are multicellular parasitic worms belonging to the nematodes (round worms), trematodes (flukes), and cestodes (tapeworms), which account for half of the WHO-designated “Neglected Tropical Diseases” and infect 1 billion to 2 billion of the world’s poorest people, with soil-transmitted helminths (gastrointestinal nematodes including *Ascaris*, *Trichuris*, and *Necator* sp.) and schistosomes (blood-dwelling trematodes) being the most common. Although great strides have been made through implementation of chemotherapy and improved sanitation, massive amounts of suffering due to helminth infections persist, and to date, no vaccines for helminths exist. Although this is probably a gross underestimation of the total, the estimated disease burden of helminth infection is at least 13,000,000 DALYs (years of life and productive life lost due to disability and/or death).

Most species do not multiply in the human host, and helminth infections increase through repeated transmission, confirming chronic susceptibility and parasite longevity. In general, the Th2 arm of the cellular immune system tends to guide the antihelminth immune response, acting through inducer and activating cytokines including Il-4, IL-5, IL-9, and IL-13. These mediators promote effector mechanisms ranging from antibodies, macrophages, and granulocytes to epithelial cell responses that tend to be less prominent in protozoal infections.

Nematodes are protected by a collagen layer that comprises the cuticle, which is overlain by a lipid-rich epicuticle and a glycoprotein surface coat. The cuticle is resynthesized and shed every time the worm enters a new developmental stage. The surface of the schistosome (trematode) is complex and varies throughout its life cycle. The outer layer consists of a tegument, a syncytial layer of cells that is bounded apically by a complex invaginated membrane. The tegument is composed of secreted lipid-rich “membranocalyx,” as well as “glycocalyx,” the latter of which is partially discarded upon transformation of cercariae to schistosomules, but also appears to be prominent on the surface of adult worms. The expression of both proteins and glycans is regulated from one life stage to the next and is highly variable.

TABLE 32.17 Proposed target profile for a malaria sexual stage and mosquito transmission-blocking vaccine[a]

Target	Comments	Issues
Indication	Prevention of transmission of *P. falciparum* or *P. vivax* (including hypnozoites)	*P. falciparum* candidates: • Gametocytes • Gametocytes and gametes • Zygotes and ookinetes *P. vivax* candidates: • Gametocytes • Gametocytes and gametes • Zygotes and ookinetes
Efficacy	>85% efficacy and reduction of the CRR below 1	Possibilities based on: (i) transmission blockage can be achieved by human immune mediators, such as immunoglobulins or cytokines, which are induced by parasite components expressed on the sexual parasite forms exposed to the human immune system during their circulation in the human body; and (ii) as observed in nature, malaria infections are able to boost primary antibody responses against gametocytes and increase the TB effects of the corresponding sera. Immunogenic proteins that are important for parasite fertilization or other vital functions of the parasite sexual forms are considered targets for TB vaccine development. Using other control tools, reduces CRR to below 1.0 for at least a year.
Duration	Effective for at least 2 yr	Need to focus on transmission impact rather than morbidity/mortality alone; may actually contain many life cycle targets (pre-erythrocytic, erythrocytic, sexual stages)
Safety	Vaccine has a safety and efficacy profile comparable to hepatitis B vaccine	Can be safely administered to pregnant women; should be no increased risk of autoimmune or other chronic diseases related to vaccination
Target population	All age groups, including pregnant women, people with immunodeficiencies, malnourished individuals, high-risk populations	May be limited to otherwise healthy people (infants, children adolescents, adults in areas of malaria endemicity)
Administration	Orally or by intramuscular of subcutaneous injection or other innovative device	Oral provides needle-free vaccination. BMP elicits type 2 response; BNP elicits type 1 response; BNP or BMP bypasses issue of tissue barriers and proteolytic environments; some studies in mice indicate blocking antibody activity of 99% with no significant differences in routes of immunization
Schedule	A single-dose schedule that can be administered by mass administration or clinic-based programs. May require booster dose after 2 yr. Minimal schedule is 3 doses, administered over 6 mo	Booster may actually be necessary 4–6 mo after the second dose and after 2 yr.
Stability, storage	Minimum shelf life 36 mo, stored at ambient temp; withstand freeze/thawing; minimum stability 30 min at 37°C, 2 yr at 2–8°C	Shelf life of at least 24 mo; vaccine vial monitor should be attached
Coadministration	No interference or interactions with other vaccines expected to be concurrently administered	Vaccine may need to be given as stand-alone product not coadministered with other vaccines.

[a] Adapted from references 89, 90, 100, and 101. BMP, biodegradable microparticle; BNP, biodegradable nanoparticle; CRR, case reproductive rate (number of individuals who can be infected from a single untreated malaria case in an endemic area); TB, transmission blocking.

TABLE 32.18 Immune responses to parasites (protozoa and helminths)[a]

Parasite or infection	Comments
Protozoa	
Intestinal protozoa *E. histolytica*, *G. lamblia*	Most organisms in gastrointestinal tract are nonpathogenic, i.e., do not elicit immune responses. *Overall immune response:* little correlation between antibody levels and protection; repeated invasion of gut wall (amebiasis) relatively common, reinfection rare in hepatic amebiasis
Leishmaniasis Self-healing dermal forms (*L. tropica*, *L. mexicana*) Nonhealing visceral forms (*L. donovani*)	In addition to two general categories, wide spectrum of disease, immune response slow to develop (few months to >1 yr); strong immunity to homologous strain, little antibody produced; visceral infections frequently progress to death; ~25% of patients do recover *Overall immune response:* cell mediated; parasite killing is intracellular and involves production of toxic metabolites by host cell; no apparent role for antibody or complement
African trypanosomiasis	Successive waves of parasitemia; antigens differ in each wave (antigenic variation); immune response rapid, efficient *Overall immune response:* agglutination, complement-mediated lysis; cell-mediated responses involved to a lesser degree
American trypanosomiasis	Incubation, 2–3 wk; acute phase, 4–5 wk; chronic phase, ≥20 yr; latent phase/no symptoms, ≥20 yr; spontaneous recovery rare (some individuals die soon after infection) *Overall immune response:* antibody involved; immunopathology is a very important aspect.
Coccidiosis	Self-limiting, immune response not that important in control but very effective against reinfection with homologous organism *Overall immune response:* antibody-mediated response probably most important; dramatic differences between immunocompetent and immunosuppressed hosts (*Cryptosporidium* spp.)
Toxoplasmosis	Antibody controls infection but will not eliminate residual organisms; no protection against reinfection, but severity reduced *Overall immune response:* probably macrophage activation reinforced by antibody; dramatic differences between immunocompetent and immunosuppressed hosts
Malaria	Time span, 2–4 yr (*P. vivax*, *P. ovale*, *P. falciparum*, *P. knowlesi*) or lifelong (*P. malariae*) *Overall immune response:* no immune response to exoerythrocytic stages; immunity does occur to homologous strains; antibody transfer effective (mother to child); strong correlation between antibody and parasite disappearance; antibodies stage specific; T cells probably serve at least two functions (assisting in antibody production and producing cytokines).
Babesiosis	Pathogenesis not fully understood; lasting immunity after infection, antibody mediated; splenic immune properties unrelated to specific acquired immunity *Overall immune response:* humoral system-mediated immune response present; impact on host cell-mediated response more important; activated macrophages important; also evidence for some immunosuppression of the host but may not be relevant to pathogenesis
Helminths	
Schistosomiasis	No evidence of spontaneous recovery, can resist infection *Overall immune response:* primary response against skin penetration by schistosomula, effective against reinfection; six methods have been identified: (i) IgG + neutrophils, (ii) IgG + eosinophils, (iii) IgG + macrophages, (iv) IgG + eosinophils + mast cells, (v) IgE + macrophages, (vi) IgE + eosinophils + mast cells *In vitro* studies indicate that eosinophils bind to schistosomula, extrude hydrolytic enzymes onto surface of worm, disrupt membrane, allow eosinophils into body, and detach tegument; macrophages become involved after damage by eosinophils and neutrophils; mechanisms probably similar in human disease. *Most important components:* hypersensitivity responses are initiated by eggs trapped in the tissues (granulomas and local tissue damage, particularly in the liver); blockage of blood flow can cause portal hypertension and vascular abnormalities.
Cestode infections	Adult forms show no evidence of acquired immunity; in larval forms, immunity is slow to develop. *Overall immune response:* larval forms evade immune response; animal studies indicate eosinophils and mast cells involved in damage to cyst, with subsequent encapsulation by various cells including macrophages; early part of immune response may be similar to that seen in schistosomiasis; larval forms exert immunosuppressive effects on the host such as larval secretions inhibiting T-cell proliferative responses and IL-2 production, preventing accumulation of inflammatory cells, and interfering with normal macrophage functions

(continued)

TABLE 32.18 *(continued)*

Parasite or infection	Comments
Intestinal nematodes	Strong immune response to all intestinal nematodes (elicited by migrating larvae); self cure (spontaneous elimination of adult worms in gastrointestinal tract); worm infections elicit Th2-subset responses, cytokines generate inflammatory responses (IgE, mast cells, and eosinophils), which are powerful mediators of intestinal inflammation *Overall immune response:* some evidence of acquired immunity and resistance to reinfection; immune system mechanisms stage specific; possible attachment of antibody and perhaps complement followed by cell attachment which damages cuticle, followed by phagocytosis by macrophages; increased IgE levels seen
Toxocariasis	
Visceral	Prolonged and severe T-cell-dependent eosinophilia; rapid, vigorous, prolonged humoral response; elevated IgG anti-A and anti-B blood group antigen titers present; elevated IgM anti-IgG (rheumatoid factor) titers may occur; elevated IgE titers
Ocular	May not be able to demonstrate circulating anti-*Toxocara* antibody; eosinophilic granulomas seen in some infections
Filariasis	Both tissue forms and microfilariae can partially evade the immune system, immunity eventually develops; strong immune responses against adult worms responsible not for protection but host pathology. *Overall immune response:* when parasites eliminated from blood, antibody can be found on surface of microfilariae; antibody initiates attack by various cells (IgG, IgE, eosinophils, neutrophils, like other helminth infections); IgE may be important in protection against larval stages but may also contribute to immunopathology via hypersensitivity reactions to adult worms; the T-cell anergy seen in patients heavily infected with lymphatic filariasis or with *Onchocerca* is probably due to down-regulation of Th1 responsiveness by IL-10.

[a]Data from references 1–3, 102.

The response of an infected host to a parasitic helminth involves both innate and adaptive immune factors and a host of cellular responses. A number of studies demonstrate a quantitative protective effect of Th2 immunity; however, it is unclear whether sterile immunity can be achieved. Unfortunately, helminths have the ability to modulate the host immune system, so that the host is required to overcome the parasite immunoregulation. Both IL-10 and TGF-β are closely related to regulatory T-cell activity, which is now becoming more evident in a number of human helminth infections.

The glycans of parasitic helminths have unique functions in innate immune responses and induce both C-type lectin receptor (CLR) signaling as well as cross talk with Toll-like receptor (TLR) signaling in the human system. The molecular mechanisms of glycan-dependent innate immune responses are also linked to the adaptive immune responses. Helminth infections and their products have a phenomenal ability to ameliorate responses to a variety of inflammatory disorders. For example, in clinical studies of patients suffering from inflammatory bowel disease, treatment with the pig nematode *Trichuris suis* caused remission of Crohn's disease for more than half of the patients and improved the symptoms of ulcerative colitis for many patients (91, 92). In addition to activating regulatory T cells to increase IL-10 and TGF-β, helminths act on other cells such as regulatory dendritic cells and macrophages, thus preventing the activation of effector T cells (lead to inflammation and disease). Third, worms seem to alter the bacterial composition of intestinal flora. Research in the mouse model indicates that helminths promote the growth of gut microorganisms considered to be "probiotics" that help maintain intestinal health (92). Recent studies have shown abrogation of multiple disease processes in the presence of helminth infection, including allergic airway inflammation, encephalitis, inflammatory bowel disease, rheumatoid arthritis, and type I diabetes in experimental models.

Enhanced allograft tolerance with helminth infection has been demonstrated in multiple species across multiple organ allograft models (mouse heart and skin; rat heart, liver, and kidney). These experimental data are consistent with historical results of skin grafting in established human schistosomiasis and supported by more recent suggestions of reduced immunosuppression requirement after liver transplantation for human *Echinococcus* infection. Thus, the possibility can now be entertained of including specific live (nonpathogenic) helminth infection, or defined products from immunoregulatory helminths, in future transplantation protocols (93).

Summary

Although there is evidence for acquired immunity in most protozoan infections, it is often neither fully effective nor protective. As with many organisms, the fact that the host does not die of overwhelming infections supports the concept of parasite immunity.

Since the majority of helminths do not multiply within the host, the host immune system is not faced with an overwhelming infection due to parasite multiplication as seen with protozoal infections. Many helminth life cycles include both larval and adult forms, both of which stimulate immune system reactions. However, adult and most larval forms are too large to be destroyed by antibody or by phagocytic cells. In this case, there may be some form of antibody-dependent cell-mediated cytotoxicity in which the parasites become coated with antibodies which bind eosinophils and other cells that destroy the parasites. Worm expulsion from the intestine is a CD4$^+$ T-cell-mediated event associated with type 2 cytokines. There tends to be less evidence for the implication of eosinophils in host protection. While type 1 or type 2 responses may be key factors following infection with intracellular protozoa or gut-dwelling nematodes, the mechanisms responsible for resistance to any one organism are usually quite specific for the biological characteristics of each.

General comments on a number of different parasites, both protozoan and helminth, are presented in Table 32.18. Although not all-inclusive, it is hoped that this chapter has provided some insight into the complex interactions between parasite and host.

Onchocerciasis
Paragonimiasis
Schistosomiasis
Strongyloidiasis
Toxocariasis
Trichinosis
Intradermal tests
Casoni test
Montenegro test

Parasitic organisms infecting humans can be divided into two classes: (i) those that multiply within the host (e.g., protozoa) and (ii) those that mature within the host but never multiply (e.g., most helminths).

Infections caused by pathogenic protozoa, which multiply within the host, are similar to infections caused by bacterial, fungal, or viral pathogens. There is continuous antigenic stimulation of the host immune system as the infection progresses. In these instances, there is often a positive correlation between clinical symptoms and serologic test results.

Some helminths migrate through the body and pass through a number of developmental stages before becoming mature adults. With rare exceptions, these infections have been difficult to confirm serologically, possibly because of a limited antigenic response by the host or failure to use the appropriate antigen in the test system. Most antigens used in serologic procedures are heterogeneous mixtures that are not well defined. The result of using such antigens may be cross-reactions or inadequate sensitivity. Examples of test formats can be seen in Fig. 33.1 to 33.8.

Antibody Detection. Although parasites and their by-products are immunogenic for the host, the host immune response is usually not protective. Any immunity that does develop is usually species specific or even strain or stage specific. Detection of antibodies in serum or cerebrospinal fluid (CSF) can be very useful as an indicator that an individual has been infected with a specific parasite. A positive result in an individual with no exposure to the parasite prior to recent travel in a disease-endemic area may be interpreted as indicating recent infection. However, detection of specific antibodies in a person native to an area of endemicity may reflect only a past infection unrelated to current clinical status. In general, detection of antibodies to parasitic diseases indicates infection at some indeterminate time and not necessarily acute or current infection. Levels of antibodies to parasites slowly decline after the patient is cured of the infection but generally last for at least 6 months to many years, depending on the infecting parasite, and thus are not generally useful, real-time indicators of successful cure.

In certain parasitic infections, the standard diagnostic laboratory procedures may not be sufficient to confirm infection or specimen collection may not be practical or cost-effective. In these circumstances, alternative methods may be helpful;

doi:10.1128/9781555819002.ch33

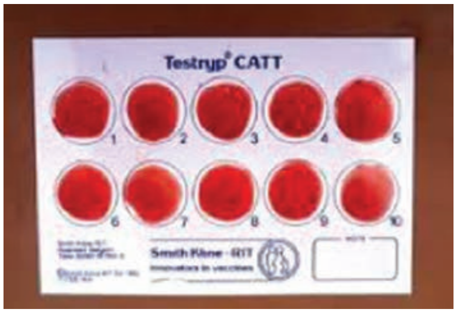

Figure 33.1 African trypanosomiasis. Card agglutination test for trypanosomiasis (CATT), antibody detection. doi:10.1128/9781555819002.ch33.f1

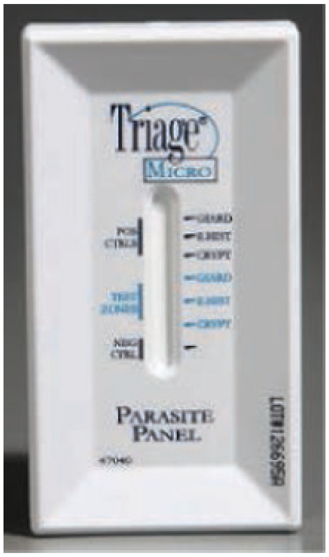

Figure 33.3 Triage rapid immunoassay. This test detects the presence of the *Entamoeba histolytica/E. dispar* group, *Giardia*, and *Cryptosporidium* spp. antigen in human fecal specimens. doi:10.1128/9781555819002.ch33.f3

these include antibody, antigen, and nucleic acid detection. In some cases, serologic methods might be clinically indicated and may be very helpful, particularly if a parasitic infection is suspected and routine results are negative. However, even with the most sophisticated technology, few serologic tests for parasitic infections can be used to confirm an infection or predict the disease outcome. Interpretation of test results may also present problems, particularly when one is dealing with patients from areas of endemic infection, who may have higher baseline titers than do patients from other areas, in whom a low titer may actually be significant. Antibody detection generally indicates exposure to the parasite at some time in the past and may not necessarily reflect a current infection. This is particularly true when testing patients who have lived in an area of endemic infection for some time; their current clinical presentation may have no relationship to a positive antibody titer for a particular parasite. Although antibody levels generally decline over a period of months to years, serologic test results neither confirm nor rule out current infection or cure.

However, a positive serologic titer to a particular parasite in a patient who has had no previous exposure to the organism is clinically relevant and probably indicates recent exposure. The importance of a complete history,

Figure 33.2 ELISA plate. Test can be used for either antibody or antigen detection; yellow color indicates a positive in this particular example. doi:10.1128/9781555819002.ch33.f2

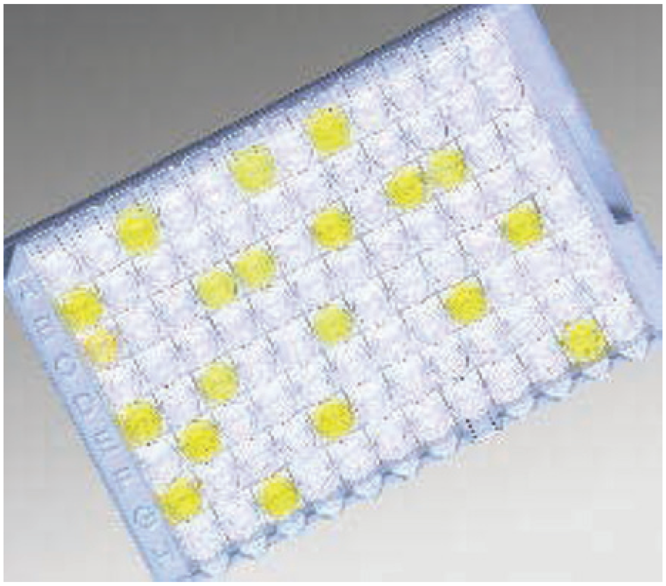

Figure 33.4 Rapid immunoassay for *Cryptosporidium* spp. This rapid cartridge format detects the presence of *Cryptosporidium* spp. antigen in human fecal specimens. The cartridge at upper left demonstrates the control spot, while the lower indicates the test is positive (second spot). doi:10.1128/9781555819002.ch33.f4

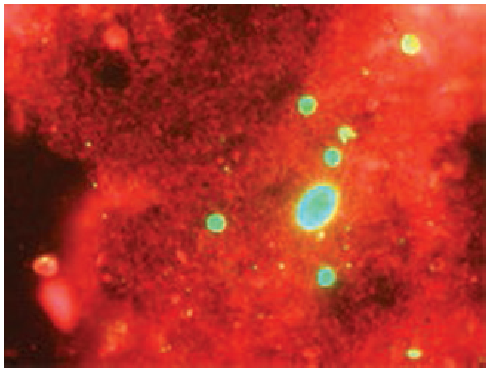
doi:10.1128/9781555819002.ch33.f5

including both residence and travel information, is critical for accurate interpretation of serologic test results. Specific reagents available for serologic diagnostic testing are listed in Tables 33.1 and 33.2.

Immunodiagnostic testing for parasitic diseases is complicated by the general assumption that serology tests for antibodies to a disease will detect all infections caused by any of the species that infect humans. That assumption is not true; some serologic tests, such as those for schistosomiasis, detect only species-specific antibodies. The same specimen can have a negative result in one test and a positive result in another.

Figure 33.6 Example of the *Giardia*/*Cryptosporidium* combination FA test result (with test [yellow-green] and counterstain [orange] colors); the large object is a *Giardia* cyst, while the smaller objects are *Cryptosporidium* spp. oocysts.
doi:10.1128/9781555819002.ch33.f6



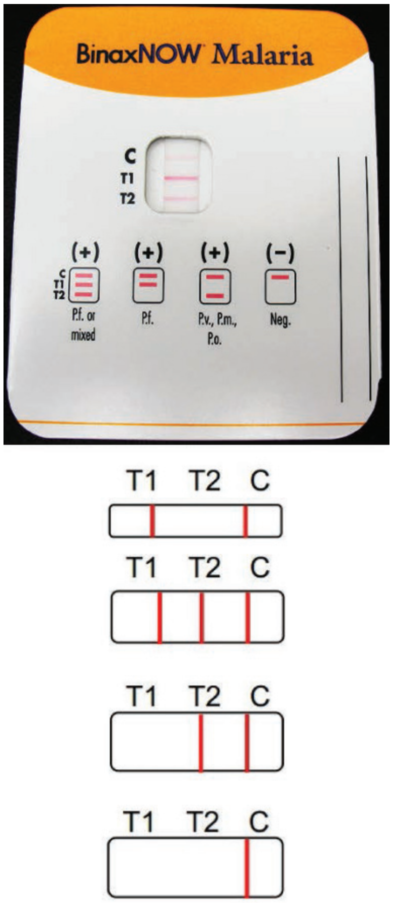


Figure 33.7 *Plasmodium* spp. rapid test (membrane flow): BinaxNOW card (upper) and the four possible results (lower). Interpretation of the four examples of results: (top set of lines) the presence of colored lines at T1 and C indicates a positive result for an infection with *P. falciparum*; (second set) the presence of three colored lines (T1, T2, and C) indicates a positive result for *P. falciparum* monoinfection or mixed infection among the four kinds of plasmodium; (third set) the presence of colored lines at T2 and C indicates a negative result for *P. falciparum* and a positive result for non-*P. falciparum* (*P. vivax*, *P. malariae*, or *P.ovale*) monoinfection or mixed infection; (bottom set) the presence of one line at C indicates a negative result. This card was not designed to detect *P. knowlesi*; however, modifications are under way. doi:10.1128/9781555819002.ch33.f7

Although serologic test procedures for parasite antibodies have been available for many years, they are not routinely offered by most clinical laboratories for the reasons mentioned above (sensitivity, specificity, and interpretation). Standard techniques that have been used include complement fixation (CF), indirect hemagglutination (IHA), indirect fluorescent antibody (IFA), enzyme immunoassay (EIA), enzyme-linked

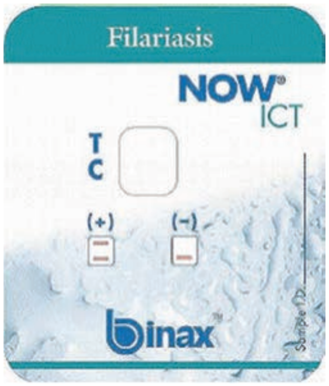

Figure 33.8 Filariasis rapid test (membrane flow). The test is also specific, as it tests for specific antigens for lymphatic filariasis and allows for the differentiation between microfilarial diseases. The most useful antigen detection test is the antigen card test known as the ICT. Not only is this test highly specific and highly sensitive, but it also quick (ready in 10 minutes), mobile, and cheap. In addition, this test can be administered during the day or night, unlike other tests that require blood samples to be taken when microfilariae are at high levels in the blood. The antigen detection test cannot differentiate between active and inactive microfilariae. Antigens can still be present in the blood if any trace of dead microfilariae remains in the circulation. Hence, a positive ICT test result may not mean the patient has active, living microfilariae in the blood. Note that if only the control line is positive, this indicates a negative result; both lines positive indicates a positive result. doi:10.1128/9781555819002.ch33.f8

immunosorbent assay (ELISA), immunoblot, soluble-antigen fluorescent antibody, bentonite flocculation, latex agglutination (LA), double diffusion, counterimmunoelectrophoresis (CIE), immunoelectrophoresis, radioimmunoassay, and intradermal tests (Table 33.3). Excellent reviews of these procedures, the rationale for their use, and their advantages and limitations are provided in references 1 and 2. Immunodiagnostic tests for amebiasis, cryptosporidiosis, filariasis, giardiasis, malaria, cysticercosis, schistosomiasis, and African trypanosomiasis have very limited commercially or U.S. Food and Drug Administration (FDA)-approved antibody detection tests available. Experimental results have been too variable due to the type of antigen preparations used (e.g., crude, recombinant purified, adult worm, egg) and also because of the use of nonstandardized test procedures. Cross-reaction leading to false-positives and misdiagnosis is also a problem, especially in regions where more than one parasite is endemic.

The Centers for Disease Control and Prevention (CDC) offers a number of serologic test procedures for diagnostic purposes, some of which are not available elsewhere. Because regulations about submission of specimens may vary from state to state, each laboratory should check with its own county or state department of public health for the appropriate instructions. Additional information on procedures, availability of skin test antigens, and interpretation of test results may be obtained directly from CDC by writing or calling:

Serology Unit
Parasitology Diseases Branch
Centers for Disease Control and Prevention
Building 4, Room 1009, Mail Stop F13
4770 Buford Highway
Atlanta, GA 30034
Serology: (770) 488-7760
Chagas' disease and leishmaniasis: (770) 488-4474
Malaria: (770) 488-7765.

General guidelines for specimen collection can be seen in Table 33.4.

Antigen Detection. For most parasitic diseases, the antigen(s) is generally the assay component which has the most influence on test sensitivity and specificity. Parasites generally have more than one life cycle stage that may have both mutually shared antigens and stage-specific antigens. The matrix to which antigens are bound for use in a specific procedure also influences which antigen subset will be available for antibody binding. During the past few years, changes in the availability of certain tests have occurred, both at the CDC and at some private laboratories. The currently available antibody and antigen detection tests are listed in Table 33.1. A number of antibody and/or antigen detection tests have been developed in the research laboratory but are not yet available commercially; these include tests for *Ancylostoma caninum*, *Angiostrongylus*, *Anisakis*, *Baylisascaris*, *Gnathostoma*, microsporidia, *Opisthorchis*, and *Trypanosoma brucei* (2). Although PCR tests have been developed for most human parasites, they are generally available only through various reference or research laboratories. As the costs of these antigen detection tests decrease and automation of the various steps is developed, there will be more interest in incorporating these methods into the routine diagnostic laboratory. A number of rapid methods are currently available for protozoa found in the intestinal tract. However, in spite of their high levels of sensitivity and specificity, there are other pathogens for which these tests are not available, including *Blastocystis* spp., *Dientamoeba fragilis*, and the microsporidia.

Molecular Methods. Progress has been made in the development and application of molecular methods for antigen detection, including the use of purified or recombinant antigens and nucleic acid probes. The detection of parasite-specific antigen is more indicative of current disease. Many of the assays were originally developed with polyclonal antibodies which were targeted to unpurified antigens that markedly decreased the sensitivity and specificity of the tests. Immunoassays are generally simple to perform and allow a large

number of tests to be performed at one time, thereby reducing overall costs. A major disadvantage of detection of antigens in stool specimens is that the method can detect only one or two pathogens at a time. One still must perform a routine ova and parasite examination to detect other parasitic pathogens. The current commercially available antigen tests have excellent sensitivity and specificity compared with routine microscopy (Tables 33.1 and 33.5).

There are several FDA-approved molecular diagnostic tests for parasites. They include the APTIMA *Trichomonas vaginalis* Assay (GenProbe, San Diego, CA). This assay utilizes the same amplification technology that has been used for years to detect *Neisseria gonorrheae* and *Chlamydia trachomatis*. It also uses the same specimen types (i.e., clinician-collected vaginal and endocervical swabs, female urine, and PreservCyt solution). It has reported high sensitivity and specificity, and does not require organism viability or motility. It, as well as other antigen-based assays, represents advances in the detection of this parasite.

The Affirm VPIII DNA probe technology (Becton Dickinson, Franklin Lakes, NJ) offers a dependable, rapid means for the early identification of three organisms causing vaginitis: *Candida* species, *Gardnerella vaginalis*, and *Trichomonas vaginalis*. During the test protocol, the assay aligns complementary nucleic acid strands to form specific, double-stranded complexes called hybrids. For each organism, this hybrid is composed of capture and color development single-stranded nucleic acid probes, complementary to the released target nucleic acid analyte. Enzyme conjugate then binds to the captured analyte.

In January 2013, the FDA approved the first test that can simultaneously detect 11 common viral, bacterial, and

TABLE 33.3 Serology-based assays: examples of various methods

Assay	Description
IHA	The indirect hemagglutination (hemagglutination inhibition) assay detects the presence of specific antiparasitic antibodies in a test serum. The serum, usually as a series of dilutions, is prepared prior to the addition of a standard suspension of erythrocytes. The highest dilution of serum that inhibits hemagglutination is the HI titer of the serum.
DFA	Primary, or direct, immunofluorescence uses a single, primary antibody, chemically linked to a fluorophore. The primary antibody recognizes the target molecule (antigen) and binds to a specific region called the epitope. The attached fluorophore can be detected via fluorescent microscopy, which, depending on the messenger used, will emit a specific wavelength of light once excited. Direct immunofluorescence, although somewhat less common, has notable advantages over the secondary (indirect) procedure. This approach has been used for the detection of antibodies to *Entamoeba histolytica*.
IFA	Indirect immunofluorescence uses two antibodies: the unlabeled first (primary) antibody specifically binds the target molecule, and the secondary antibody, which carries the fluorophore, recognizes the primary antibody and binds to it. Multiple secondary antibodies can bind a single primary antibody. This provides signal amplification by increasing the number of fluorophore molecules per antigen. This protocol is more complex and time-consuming than the primary (or direct) protocol above, but it allows more flexibility because a variety of different secondary antibodies and detection techniques can be used for a given primary antibody.
ELISA	The enzyme-linked immunosorbent assay can be performed to evaluate either the presence of antigen or the presence of antibody in a sample. Relevant antigens are attached to a surface (usually 48- to 96-well trays). Then, a serum antibody is applied over the surface so it can bind to the antigen. This antibody is linked to an enzyme, and, in the final step, a substance containing the enzyme's substrate is added. The subsequent reaction produces a detectable signal, most commonly a color change in the substrate. It is a useful tool for determining serum antibody concentrations for certain parasitic infections, such as Chagas' disease, leishmaniasis, toxoplasmosis, and some of the helminth infections.
FAST-ELISA	The Falcon assay screening test ELISA uses synthetic and recombinant peptides to evaluate antibody responses to an antigen. In the past, the method has been applied to the study of malaria, fascioliasis, schistosomiasis, and taeniasis. However, this technique is subjected to the same drawbacks as most serology-based tests. Antibodies raised against a peptide from one parasite protein may cross-react with proteins from other species. Also, antibodies against a peptide may react in some assays but not in others and some regions of a peptide may be more immunogenic than others.
Dot-ELISA	The main difference between the regular ELISA and the dot-ELISA is in the surface used to bind the antigen. In the dot-ELISA, the plastic plate is replaced by a nitrocellulose or other paper membrane onto which a small amount of sample volume is applied. The change in binding matrix improves the specificity and sensitivity of the assay by reducing the binding of nonspecific proteins when plastic binding matrixes are used. The principle is similar to the immunoblot. The dotted membrane is incubated first with an antigen-specific antibody followed by an enzyme-conjugated anti-antibody. The addition of a precipitable, chromogenic substrate causes the formation of a colored dot on the membrane which can be visually read. The dot-ELISA has been and still is extensively used in the detection of parasitic diseases, including amebiasis, babesiosis, fascioliasis, cutaneous and visceral leishmaniasis, cysticercosis, echinococcosis, malaria, schistosomiasis, toxocariasis, toxoplasmosis, trichinosis, and trypanosomiasis. In the last few years, published studies have demonstrated the use of the dot-ELISA for the detection of *Fasciola gigantica*, *Trypanosoma cruzi*, and *Trypanosoma brucei*.
LIPS	The luciferase immunoprecipitation system is a modified ELISA-based assay; serum containing antigen-specific antibodies can be identified by measuring light production. An antigen is fused to the enzyme reporter Renilla luciferase (Ruc) and expressed as a Ruc-fusion in mammalian cells to allow for mammalian-specific posttranslational modifications. The crude protein extract is then incubated with the test serum and protein A/G beads. During the incubation, the Ruc-antigen fusion becomes immobilized on the A/G beads, which allows the antigen-specific antibody to be quantitated by washing the beads and adding coelenterazine substrate and measuring light production. LIPS has been used for the identification of serum samples containing *Strongyloides stercoralis* and *Loa loa* antibodies. Some of the advantages of the LIPS technology include its rapidity and accuracy in detecting infected patients.
IB	When the immunoblot (Western blot) is used, a specific protein is transferred to a nitrocellulose membrane, nonspecific sites are blocked, and the protein is probed with serum samples. In the case of testing for *Baylisascaris* antibodies, the serum was diluted at 1:100. For high-throughput testing of sera, 6 µg of rBpRAG1 protein was separated on NuPage one-dimensional-well 4–12% Bis-Tris gradient gels (Life Technologies) and transferred to nitrocellulose membranes for Western blot analysis by using a Mini-Protean II multiscreen apparatus (Bio-Rad Laboratories). Human serum and CSF specimens were tested at dilutions of 1:100 and were incubated with HRP-conjugated anti-human IgG at 1:5,000. The membranes were incubated with DAB-H2O2 solution. NOTE: The lack of cross-reactivity in the rBpRAG1 assay eliminates the need for additional testing to rule out toxocariasis and increases the confidence in a baylisascariasis diagnosis.[a]

[a] Adapted from reference 101.

TABLE 33.4 Specimen collection and shipment for antibody and antigen detection tests

Type of test requested	Collection	Shipment
Antibody detection		
Most parasites	Serum or plasma acceptable	All specimens can be shipped at room temperature to arrive within several days; if specimen is small (<1.0 ml), shipment with dry ice is recommended to prevent specimen evaporating during shipment; in general, acute- and convalescent-phase sera are not required; not all laboratories are equipped to perform testing on eye fluids or CSF; advisable to call to confirm availability if other than CDC
Toxocariasis, toxoplasmosis	Aqueous and vitreous eye fluids accompanied by serum	
Central nervous system infections (cysticercosis, toxoplasmosis)	CSF accompanied by serum	
Antigen detection		
Fresh or formalinized stool	Routine stool collection vials	Some diagnostic kits require fresh stool; advisable to check with the laboratory prior to specimen submission

parasitic (*Cryptosporidium*, *Giardia*) causes of infectious gastroenteritis from a single patient sample (xTAG Gastrointestinal Pathogen Panel; Luminex, Inc., Austin, TX). The xTAG GPP is a multiplexed nucleic acid test that detects various causes of gastroenteritis, inflammation of the stomach, and intestines.

The BioFire FilmArray Gastrointestinal Panel is another FDA-approved multiplex PCR test that can simultaneously detect 22 gastrointestinal pathogens in about an hour (BioFire, Salt Lake City, UT). The panel includes *Cryptosporidium* sp., *Cyclospora cayetanensis*, *Entamoeba histolytica*, and *Giardia lamblia*, along with a number of bacteria and viruses.

There are also a number of other molecular tests that are in clinical trials for the detection of select gastrointestinal parasites. These tests are molecular gastrointestinal panels and target the most commonly occurring bacterial, viral, and parasitic stool pathogens. Although there are laboratory-developed tests for most parasites, these are not commercially available or available only in specialized testing centers. When such tests are used, there should be attention given to the use of internal amplification controls to detect inhibition, since common specimens, such as blood and stool, may contain PCR inhibitors. Thorough validation is required before these are implemented for clinical testing.

Protozoal Infections

Amebiasis

The causative agent of amebiasis, *Entamoeba histolytica*, is found throughout the world and is a major infectious disease in developing countries. Although this parasite is considered mainly a cause of diarrhea, the trophozoite stage can readily invade tissues, resulting in the development of extraintestinal disease.

The diagnosis of infection with *E. histolytica*/*E. dispar* is usually based on finding either trophozoite or cyst stages in the stool. However, unless the trophozoites contain ingested red blood cells (RBCs), morphologic differentiation between pathogenic *E. histolytica* and nonpathogenic *E. dispar* is not possible. Antigen detection may be helpful as an adjunct to routine microscopy, either for detection of the *E. histolytica*/*E. dispar* group or for detection of pathogenic *E. histolytica*. In extraintestinal amebiasis, one may or may not find organisms in the stool. The diagnosis of extraintestinal amebiasis depends largely on serologic tests for antibody detection.

The discovery that there are two distinct but morphologically identical species of *Entamoeba* infecting humans is important. *E. dispar* is associated with the asymptomatic carrier state and is the most prevalent species, whereas *E. histolytica* is the pathogenic form capable of invading tissue and causing symptomatic disease. Through the use of RNA and DNA probes, the genetic difference between these two species has been substantiated. At present, when a form resembling *E. histolytica* is detected in fecal material, it is not possible to differentiate it from *E. dispar* unless the trophozoite contains ingested RBCs.

Antibody Detection. If IgG antibodies specific to *E. histolytica* are detected, tissue invasion has occurred and may represent past or present disease. Serum antibodies can be detected in 85 to 95% or more of the patients with invasive disease. In newborns, maternal antibody disappears within 3 months, and persistence of antibody after this time may indicate active extraintestinal disease.

The most commonly used serologic tests are IHA, IFA, CF, ELISA, LA, CIE, and immunodiffusion (ID). CF tests have not been widely used because of nonspecific and variable results. IHA and LA appear to detect the same antibody. Although ELISA and IHA are two of the more sensitive tests, antibody titers persist for years, making interpretation difficult in certain patients. ELISA and IHA are useful for epidemiologic surveys. IFA and ID not only are sensitive tests but also have high positive predictive values. After successful therapy, titers in many of the patients decrease, allowing physicians to monitor the therapeutic response. Although tests for the detection of IgM antibodies specific

for *E. histolytica* have been reported, their clinical usefulness is questionable because of the lack of sensitivity. Many of the current tests use crude trophozoite extracts, whereas a few use recombinant proteins (3).

IHA has for many years been the standard for the diagnosis of extraintestinal amebiasis; titers of ≥1:256 are seen in 95% of patients with extraintestinal amebiasis, 70% of patients with active intestinal disease, and 10% of asymptomatic cyst passers. Unfortunately, titers can persist for many years after successful therapy, and so the presence of a titer does not automatically indicate active disease. However, false-positive results at titers of >1:256 rarely occur. The sensitivity of detection of specific antibodies to *E. histolytica* in serum is reported to be near 100%, which is promising for diagnosis of amebic liver abscess (ALA) (4). Serum anti-lectin IgG antibodies could be present within 1 week after the onset of symptoms in patients with amebic colitis and ALA, with a value over 95%.

Recombinant proteins such as the 170-kDa subunit of the galactose-inhibitable adherence lectin have been used to detect serum antibodies in more than 95% of patients with ALA. PCR and DNA hybridization assays have been used to detect specific gene sequences related to pathogenic *E. histolytica;* however, none are commercially available at this time.

In most laboratories, EIA (ELISA) has replaced other test formats; the EIA is equally sensitive and specific. The sensitivity of the EIA varies with the disease process such that 90 to 100% of individuals with extraintestinal amebiasis are positive while only 70 to 80% of those with invasive disease limited to the intestine are positive. Significant antibody titers may take 10 to 14 days to develop even with documented invasive amebiasis. Since positive titers may persist for many years after infection, a single test result must be interpreted with caution when prior infection is possible.

Antigen Detection. Antigen-based fecal immunoassays have several significant advantages over other methods currently used for diagnosis of amebiasis: (i) some of the assays differentiate *E. histolytica* from *E. dispar*; (ii) they have excellent sensitivity and specificity; (iii) they are readily usable by most laboratory personnel; and (iv) these assays have potential use as screening tools in situations such as waterborne outbreaks. Because there are distinct genetic differences between *E. dispar* and *E. histolytica*, commercial kits have been developed to detect their presence and differentiate them in clinical samples (Table 33.5). However, current antigen detection tests require the examination of fresh or frozen (not preserved) stool specimens, while many laboratories have switched to stool collection methods using various preservatives.

Other specimens in which amebic antigens have been detected include saliva, serum, and abscess fluid. With ELISA, the adherence lectin antigen has been detected in saliva samples of ALA patients. This assay was found to be 22% sensitive and 97.4% specific. Amebic antigen in pus specimens from ALA patients was detected by ELISA (4).

A coagglutination test for the detection of circulating antigen in sera from patients with ALA has been reported (5). This is a simple and economical slide agglutination test. In patients with ALA, 45 (90%) of 50 sera were positive by the coagglutination test, while none of the 25 control sera was positive. However, two false-positive results were seen with two sera from patients with other parasitic and miscellaneous infection controls. Although this test is not yet commercially available, it could be used as a sensitive and specific rapid slide agglutination test for the presence of amebic antigen in the sera; it would also be useful in a routine clinical laboratory setting. Several of the new automated enteric panels include testing for amebiasis (*Entamoeba histolytica*); additional information can be found in Appendix 8.

Babesiosis

Definitive diagnosis of babesiosis may be difficult because of the small number of infected RBCs, or the inability to discriminate between *Plasmodium falciparum* and *Babesia* spp. Babesiosis is transmitted by ticks, which can also transmit *Borrelia burgdorferi* and *Ehrlichia* spp. There are reports of coinfection with these three disease-causing agents (6). Although *Babesia microti* is the primary cause of human babesiosis in the United States, at least four other species have been associated with human infections including *Babesia duncani*, *Babesia* sp. CA-type, *Babesia* sp. MO1, and newly discovered *Babesia* sp. from a patient in Tennessee (7). Four severe to fatal human cases with *Babesia* sp. CA-type have been reported in splenectomized patients from California (8). This species is morphologically indistinguishable from *B. duncani*, but can be distinguished by genetic sequencing of multiple targets. In the United States, serologic tests for *B. microti* are considered sensitive and specific because the other *Babesia* that infect humans in the United States (i.e., *B. duncani*, *Babesia* sp. CA-type, and *Babesia* sp. MO1) have limited reactivity with *B. microti* antigens. But, as new *Babesia* species are discovered, serologic cross-reactivity may be observed.

The serologic response to acute infection is marked by a rise in the titer to ≥1:1,024 during the first few weeks, followed by a gradual decline to 1:16 to 1:256 over a period of 6 months. Infections caused by a strain of *Babesia* found in the western part of the United States may not yield a diagnostic titer (9) and would represent a false-negative result. When tested for babesiosis by IFA, patients infected with malaria have been noted to yield a serologic cross-reaction, generally of low titer; however, the test is 100% specific for patients with other tick-borne infections or patients with no exposure to the organism. Titers of ≥1:64 indicate infection with *B. microti*. Titers may persist for 6 to 12 months after acute illness. A titer range of 1:64 to 1:256 suggests an infection probably more than 6 months ago. However, a titer of ≥1,024 indicates a relatively recent infection.

PCR has also been used to detect infections (10). Despite the present unavailability of commercially available screening assays, some form of serologic and nucleic acid testing for *Babesia* spp. may be justified. Assuming that interactions between humans and ticks will probably increase in the future, it is likely that both new and extant tick-borne agents pose potential threats to transfusion safety (11).

Chagas' Disease

Trypanosoma cruzi infects millions of people in Central and South America and is a significant public health problem there. Screening of blood donors in areas where Chagas' disease is endemic is very important. In addition, donor centers are concerned about contamination of the blood supply when donors are migrant workers or immigrants who resided in areas where infection is endemic. Definitive diagnosis depends on demonstration of the parasite in blood or tissues. However, examination of blood may be helpful only during the initial acute disease or during chronic exacerbation. During chronic Chagas' disease, serologic testing may be the only method of detecting the infection.

Antibody Testing. Serologic tests used for the diagnosis of Chagas' disease include CF (Guerreiro-Machado test), IFA, IHA, ELISA, and agglutination. Cross-reactions with low titers have been noted with leishmaniasis, infectious mononucleosis, lepromatous leprosy, pemphigus foliaceus, and *Trypanosoma rangeli* infections.

Although the IFA test is more sensitive than the CF test, the CF test is more specific. ELISA kits which use crude antigens have sensitivities and specificities similar to those of IFA. For chronic trypanosomiasis, sensitivity is good and negative serology is helpful to exclude the diagnosis. In acute cases of *T. cruzi*, the sensitivity is lower because it takes from 2 to 8 weeks to develop a detectable antibody titer. The specificity of the test is reasonable but cross-reactions with leishmaniasis and syphilis were observed.

Use of synthetic peptides and recombinant antigens has improved the sensitivity and specificity of these diagnostic techniques (12, 13). Tri- and tetrapeptides, representing immunodominant epitopes of *T. cruzi*, have been used in the ELISA format to detect serum antibodies. These tests showed much higher rates of sensitivity and specificity and may serve as excellent alternatives to lysate for detection of anti-*T. cruzi* antibodies, as required for developing blood-screening assays (14, 15). Recombinant antigen-based assays have been used for the detection of IgM and IgA antibodies in congenital Chagas' disease and for the evaluation of therapy (16).

In one study to determine the prevalence of Chagas' disease among donors in five Mexican blood banks, two commercial serologic assays for Chagas' disease, the Abbott Chagas EIA and the Meridian Chagas' IgG ELISA, were tested. It is obvious from the data that transfusion-associated transmission of *T. cruzi* is occurring in the study areas. Serologic testing of blood donors for Chagas' disease should be performed there and in the rest of Mexico. However, the two screening assays evaluated may lack the accuracy necessary for blood donor testing when used as suggested by the manufacturers (17).

Routine blood donor screening for *T. cruzi* with a single test results in unacceptable numbers of false-negative samples in areas of highly endemic infection or in at-risk population groups. Adding a second test seems mandatory, but selection depends on local costs and feasibility (18). Because of the risk of transfusion-related infections and the lack of adequate screening tests to detect *T. cruzi*-positive donors, PCR may become the test of choice for screening (19).

Radioimmunoprecipitation assay (RIPA) has been used in the United States as the "gold standard." Although these tests are sensitive and specific, there is a need for a rapid, sensitive, and specific diagnostic test for screening surveys or use in small rural clinics or in cardiac transplantation situations. Such a test needs to maintain a high level of sensitivity and specificity irrespective of geographical location. Using recombinant proteins, a lateral flow assay was performed with the ITC6 recombinants as the solid-phase antigen in the test line. An affinity-purified goat anti-human IgG antibody was labeled with colloidal gold and used as the mobile phase. The control line comprised recombinant protein A. The ITC8.2 assay was shown to have a high correlation with the confirmatory RIPA used in the United States and demonstrates improved reactivity with *T. cruzi*-positive sera from Central American and U.S. blood donors compared to TcF (20).

There are currently two FDA-approved assays for the detection of *T. cruzi* antibodies. The ABBOTT PRISM Chagas EIA (Abbott Laboratories, Abbott Park, IL) is intended to screen individual human donors, including volunteer donors of whole blood and blood components and other living donors, for the presence of antibodies to *T. cruzi*. The assay is also intended for use in testing serum and plasma specimens to screen organ donors when specimens are obtained while the donor's heart is still beating, and in testing blood specimens to screen cadaveric (non-heart-beating) donors. In a study of sensitivity and specificity in a high-risk population, the ABBOTT PRISM Chagas assay demonstrated a 98.47% sensitivity and a specificity of 98.72%.

The ORTHO T. cruzi ELISA (Ortho-Clinical Diagnostics, Inc., Raritan, NJ) is for the qualitative detection of antibodies to *T. cruzi* in human serum, plasma, and cadaveric specimens, similar to the Abbott product. The ORTHO T. cruzi ELISA Test System is intended for use in a fully manual mode, in semi-automated mode using the Ortho Summit Sample Handling System (Summit), or in automated mode with the Ortho Summit System. Sensitivity was 99.99% from normal blood donors and 100% when tested from countries with endemic *T. cruzi*. Specificity from the high-risk population was 99%. These products are not approved for pooled blood or processed plasma and products made from such pools (FDA: http://www.fda.gov/BiologicsBloodVaccines/BloodBloodProducts/ApprovedProducts/LicensedProductsBLAs/BloodDonorScreening/InfectiousDisease/UCM080466#anti_Tcruzi_Assays, accessed 19 June 2014).

Antigen Testing. Circulating-antigen detection methods have been used to detect recently acquired and congenital infections. PCR has greater sensitivity and specificity than routine methods for the diagnosis of Chagas' disease and can detect as few as one trypomastigote per 20 ml of blood (21, 22). PCR has been very useful in diagnosing acute and chronic Chagas' disease and in monitoring therapy (23).

Cryptosporidiosis

Antibody Testing. In addition to waterborne outbreaks, *Cryptosporidium* infections commonly occur in pediatric and immunocompromised individuals. Serologic tests for antibody for the diagnosis of this infection have not been useful; however, an immunoblot assay has shown specific antigen-antibody banding patterns in individuals presumed to be infected. Using the immunoblot assay as the gold standard, new ELISAs have been shown to be more specific and, with the 27-kDa antigen ELISA, more sensitive than the crude oocyst antigen ELISA currently being used (24). Unfortunately, these reagents are not readily available. Detection of IgG antibodies in sera from patients with *C. parvum* and *C. hominis* has been reported using two sporozoite antigens (15/17 kDa and 27 kDa). Overall responses to the 15/17-kDa antigen complex were stronger and over a greater range than those to the 27-kDa antigen, but declined between 181 and 240 days and were barely detectable thereafter. Responses to the 27-kDa antigen were much weaker but remained detectable for a greater length of time. No differences were detected in either antibody response to infection with *C. hominis* or *C. parvum*. Strong responses with the 15/17-kDa antigen occurred within 6 months of infection (25). A multiplex assay detected IgG antibodies against *Giardia* and *C. parvum* antigens (26).

Antigen Testing. Detection of the organism in stool specimens relies on the use of special staining techniques or fecal immunoassays. Permanent stains normally used in ova and parasite examinations do not adequately stain *Cryptosporidium* spp. A number of commercially available immunoassay kits for antigen detection are available and are more sensitive and specific than routine microscopic examination (27–35) (Table 33.5). Stool specimens may be fresh, frozen, or fixed; however, polyvinyl alcohol-fixed specimens are usually unacceptable for use in the fecal immunoassays. Based on published information, sensitivity and specificity data tend to be comparable for the EIA, FA, and rapid cartridge formats for the detection of *Cryptosporidium* spp. antigen in fecal specimens. In general, PCR has proven to be more sensitive than microscopy and antigen detection immunoassays; however, cost and time remain issues for improvement. Several of the new automated enteric panels include testing for cryptosporidiosis (*Cryptosporidium* spp.); additional information can be found in Appendix 8.

Cyclosporiasis

Currently, there are no manual immunodiagnostic tests available for cyclosporiasis. However, water concentrates have been subjected to community DNA extraction followed by PCR amplification, PCR sequencing, and computer database homology comparison for the detection of *Cyclospora cayetanensis* (37). Also, the BioFire FilmArray Gastrointestinal Panel (bioMérieux, Marcy l'Etoile, France) is designed for the simultaneous detection of 22 different enteric pathogens directly from stool specimens, including *Cyclospora cayetanensis*. This test is a qualitative test and does not provide a quantitative value for the organism(s) in the sample. The FilmArray GI pouch is a closed-system disposable that houses all the chemistry required to isolate, amplify, and detect nucleic acids from multiple gastrointestinal pathogens within a single stool specimen (see Appendix 8).

Giardiasis

Giardia lamblia can cause chronic diarrhea and malabsorption, especially in children. The organism is one of the most easily recognized parasites when detected in the stool; however, variability in the concentration of organisms in the stool makes this infection difficult to diagnose.

Antibody Detection. Serum antibodies to *G. lamblia* have been detected in infected patients; however, because of the lack of sensitivity, they cannot be recommended for diagnosis. After successful therapy, antibodies can be detected for as long as 15 months. Studies show intriguing associations between seroprevalence, outbreak-related laboratory serologic data, and patterns of parasite contamination of drinking water. However, additional studies are required to validate the serologic approach to risk assessment of waterborne parasitic infections at a community level (26, 37).

Antigen Detection. Antigen detection in stool, duodenal fluids, and serum by direct FA, IFA, ELISA, and immunoblotting methods has been reported (27–35). These tests are reliable and as sensitive as routine ova and parasite examinations. Commercial immunoassay kits are readily available (Table 33.5). Users will have to evaluate which kit will be most useful for their own laboratories (38). Some of the methods may require fresh specimens, and stools fixed in preservatives may not be suitable. Also, some of the kits may not detect both trophozoites and cysts of *G. lamblia* but may be selective for only one life cycle stage. In one case, the fecal antigen detection kit for fresh or frozen specimens detects but does not differentiate *Giardia*, *Cryptosporidium*, and *E. histolytica* (35). In a recent assessment of two real-time PCR assays, the Verweij real-time PCR was robust, very sensitive, and suited for use as a first-line diagnostic test for giardiasis (39). Several of the new automated enteric panels include testing for giardiasis [*Giardia lamblia* (*G. duodenalis*, *G. intestinalis*)]; additional information can be found in Appendix 8.

Leishmaniasis

Leishmania spp. are obligate intracellular parasites that are transmitted to the mammalian host by the bites of infected sand flies. Leishmaniasis is mainly a zoonosis, although in certain areas of the world there is primarily human-vector-human transmission. The World Health Organization estimates that 1.5 million cases of cutaneous leishmaniasis and 500,000 cases of visceral leishmaniasis (VL) occur every year in 82 countries. Estimates indicate that approximately 350 million people are at risk for acquiring leishmaniasis, with 12 million currently infected.

Leishmaniasis refers to a diverse group of diseases, with the spectrum of disease depending on the infecting species. Disease syndromes range from self-healing cutaneous lesions to debilitating mucocutaneous infections to subclinical viscerotropic dissemination to fatal visceral involvement. Since disease presentations vary considerably, a well-defined classification system based on clinical findings is difficult and sometimes confusing. With recent outbreaks in many areas of the world, including Brazil, India, Italy, Spain, Sudan, and Kenya, leishmaniasis has become more widely recognized as an important emerging infectious disease in many developed as well as developing countries.

The taxonomy of *Leishmania* spp. is controversial and reflects the development of multiple parameters on which classification is based. Previously, organisms were classified based on the clinical disease picture and geographic locations; with the development of criteria based on biochemical and genetic data, the taxonomic groupings no longer coincide with recognized disease entities.

Antibody Detection. A number of serologic diagnostic methods have been developed worldwide, although they are not widely available. In general, sensitivities are >90% but specificities are lower. False-positive results can be seen with other infectious diseases, following treatment for VL where antibodies persist for months, and in some asymptomatic patients. There are currently four tests in use, direct agglutination (DA), IFA, CIE, and ELISA. DA appears to be the best choice as a diagnostic tool, is very specific, and does not require expensive equipment or reagents. However, patients may still have positive sera for 1.5 to 5 years after treatment (40). DA has also been adapted to filter paper sampling, and the filter paper eluates compare well with their homologous sera and correlate strongly with antibody titers. However, newer studies using ELISA formats indicate excellent sensitivity and specificity and may be very helpful in early infections.

Currently, IFA is used to detect antibodies to *Leishmania* spp. but cannot differentiate among the various species. However, it can differentiate leishmaniasis from other similar diseases, although some cross-reactivity occurs with *T. cruzi* (the cause of Chagas' disease), leprosy, malaria, and schistosomiasis. Sensitivity is excellent for VL (>90%) but much less so for cutaneous and mucocutaneous leishmaniasis.

The humoral response in patients coinfected with HIV and *Leishmania* is much lower than that in immunocompetent patients; the immunoblot method appears to be sensitive, noninvasive, and specific for the diagnosis of VL in immunocompromised patients (41). IgG titers of 1:16 or greater are considered positive, but provide only suggestive support for the diagnosis of *Leishmania*. The sensitivity of the test is reasonable for VL. The gold standard remains the identification of *Leishmania* amastigotes in stained smears of material aspirated from cutaneous lesions, spleen, bone marrow or other sites. This involves biopsy histology, PCR, and culture.

A previously described ELISA that detects patient antibodies reactive with the recombinant *Leishmania* protein K39 (rK39) has been modified to confirm suspected kala azar (VL) and to detect asymptomatic infection in a community study in Bangladesh. The sensitivity and specificity of the modified ELISA for kala azar were 97.0% and 98.9%, respectively, for sera from the study population (42). Using the rapid rK39 test (Kalazar Detect; InBios International, Seattle, WA) for the detection of VL, results showed a high specificity but only moderate sensitivity; those patients living in an area of endemicity who have a negative test should be evaluated further with additional serological tests and examination of bone marrow aspirates (43).

Antigenic properties of a chimeric recombinant antigen have been evaluated by indirect ELISA using a panel of human and canine sera previously characterized by parasitologic and/or serologic techniques. Chimeric ELISA showed 99% specificity in both human and canine control groups, while the sensitivity was higher in canine VL than in human VL. Results suggest the potential use of this new antigen for routine serodiagnosis of VL in both human and canine hosts (44).

Post-kala azar dermal leishmaniasis (PKDL) is a dermal complication of kala azar. Diagnosis of PKDL is difficult due to the low parasite burden in the lesions. The DA test was compared with those of the rK39 strip test. The sensitivities of the DA test for antileishmanial antibody detection, based on promastigote and amastigote antigens at a cut-off titer of 1:800, were 98.5% and 100%, respectively, with corresponding specificities of 96.5% and 100%. The DA test could correctly detect 100% of polymorphic cases and 95.4% of macular PKDL cases. In comparison, the rK39 strip test was able to correctly diagnose 95.6% of polymorphic and 86.0% of macular PKDL cases. A DA test based on axenic amastigote antigen provided 100% sensitivity and specificity, making it particularly useful for macular PKDL cases, which are often missed by the rK39 strip test. Thus, the DA test is simple, reliable, and inexpensive for PKDL diagnosis and has potential applicability in field conditions (45).

Antigen Detection. Diagnosis of VL is usually confirmed by demonstration of organisms in tissue smears. However, obtaining the specimens may be difficult. Antibody-based diagnostics are limited by their inability to predict active disease. A new LA test (KAtex; Kalon Biological Ltd., Guildford, United Kingdom), which detects parasite antigen in freshly voided and boiled urine, has been evaluated for use with VL patients before and after treatment. KAtex appears to be a promising test, which in this simplified and improved format could be useful in the diagnosis of VL (46, 47). Antigen detection in urine by KAtex is appropriate for primary diagnosis of VL, for monitoring the efficacy of treatment, and for detection of subclinical infection.

Circulating antigens in 35 serum samples from patients with VL were successfully identified using dot-ELISA, giving 100% sensitivity. With the exception of serum samples from patients infected with *Plasmodium vivax*, which has shown cross-reactivity with *Leishmania donovani* antigens, the test appeared to be specific for the detection of circulating leishmanial antigens (48). The dot-ELISA is highly sensitive and specific, inexpensive, and easy to interpret visually, making it an excellent screening test for the surveillance and diagnosis of kala azar in the field (49).

Malaria

Malaria is known to infect more than 250 million individuals throughout the world and kills more than 1 million people a year, most of whom are children. The vector for malaria is the female anopheline mosquito. When the vector takes a blood meal, sporozoites contained in the salivary glands of the mosquito are discharged into the puncture wound. Within an hour, these infective stages are carried via the blood to the liver, where they penetrate parenchymal cells and begin to grow, thus initiating the pre-erythrocytic or primary exoerythrocytic cycle. The sporozoites become round or oval and begin dividing repeatedly. This schizogony results in large numbers of exoerythrocytic merozoites. Once these merozoites leave the liver, they invade the RBCs, initiating the erythrocytic cycle. It has been reported that in *P. vivax* and *P. ovale*, a secondary or dormant schizogony may occur from organisms that remain quiescent in the liver until a later time. These resting stages are termed hypnozoites. Delayed schizogony does not occur in *P. falciparum* and probably does not occur in *P. malariae* or *P. knowlesi*.

Clinical symptoms of malaria include anemia, splenomegaly, and the classic paroxysm, with its cold stage, fever, and sweats. Although the febrile paroxysms strongly suggest infection, many patients who are seen in medical facilities, particularly in the early stages of the infection, do not exhibit the typical fever pattern. They may have fever or several small, random peaks each day. Since the symptoms associated with malaria are so nonspecific, the diagnosis should be considered in any symptomatic patient with a history of travel to an area where malaria is endemic. The typical paroxysm begins with the cold stage and rigors, which last 1 to 2 h. During the next few hours the patient spikes a high fever and feels very hot, and the skin is warm and dry. The last several hours are characterized by marked sweating and a subsequent drop in body temperature to normal or subnormal.

Giemsa-stained thick and thin blood films have been used to diagnose malaria for many years and have always been considered the gold standard. However, a number of alternative methods have been developed, including different approaches to microscopy, flow cytometry, biochemical methods, immunoassay, and molecular methods. The aim of these procedures has been to reduce cost, reduce the need for expensive equipment, increase sensitivity, and provide simple, rapid methods that do not require conventional microscopy.

Antibody Detection. Serodiagnosis is not recommended for the diagnosis of malaria except in cases of transfusion reaction, where the parasitemia is so low that malaria transmission via blood transfusion cannot be documented. For a patient with repeated negative blood smears, serologic testing may be indicated, but the presence of antibody does not correlate with past or present infection.

In regions of low immunity, serologic assays offer an efficient method to identify infectious donors. The recent development of EIAs with improved sensitivity to *P. falciparum* and *P. vivax*, the predominant transfusion threats, has improved the possibility of serologic testing. Although universal serologic screening in regions where malaria is not endemic is not cost-effective, targeted screening of donors identified to be at risk based on travel-based questioning can significantly reduce wastage through reinstatement. Importantly, transfusion safety does not appear to be compromised by this approach, as evidenced by the lack of a documented transmission in France between 1983 and September 2002, where such a strategy has been used since 1976 (50). Malarial parasitemias in healthy donors occur; thus donor malaria-risk strategies must take into account the possibility of such donors. Countries not using malarial antibody screening should consider carefully the collection of donations from donors previously resident in countries of endemicity; temporary deferral is insufficient (51).

IFA should be used only for the diagnosis of idiopathic tropical splenomegaly syndrome (hypertrophic malarial splenomegaly). This test should not be used to diagnose malaria attacks. The gold standard for acute malaria remains the malaria smear (e.g., thin, thick, buffy coat) or antigen capture techniques or PCR. Antibody titers may persist for years after therapy. Titers for tropical splenomegaly syndrome can be extraordinarily high (e.g., 1:125,000) and decline slowly after therapy.

Antigen Detection. The substitution of newer, more expensive drugs mandates rapid, accurate, and inexpensive diagnostic procedures so that directed therapy can be provided. Rapid diagnostic tests for malaria are being used in many areas of the world. Currently, the World Health Organization recommends treatment of confirmed malaria cases only, rather than providing presumptive treatment. Therefore, diagnostic testing becomes an important issue in the management of malaria.

Malaria is a serious parasitic disease, particularly in the nonimmune traveler, and prognosis depends on timely diagnosis. Microscopy remains the gold standard of diagnosis; however, malaria rapid diagnostic tests (RDTs) are increasingly used in nonendemic settings. Malaria RDTs, sometimes called "dipsticks" or malaria rapid diagnostic devices (MRDDs), are used in the diagnosis of malaria by providing evidence of the presence of malaria parasites in human blood. RDTs are an alternative to diagnosis based on clinical grounds or microscopy, particularly where good-quality microscopy services cannot be readily provided; currently, there are more than 200 RDTs available commercially. RDTs are lateral flow immunochromatographic antigen-detection tests which rely on the capture of dye-labeled antibodies to produce a visible band on a strip of nitrocellulose. Extensive lists of malaria RDTs can be found on the following site (http://www2.wpro.who.int/NR/rdonlyres/3B0EEC88-A85A-4C66-BED8-46F13F47D087/0/RDT_selection_criteria2012.pdf; last accessed 20 June 2014). Reported sensitivities vary between different RDT products but are generally good for *P. falciparum*, with RDTs detecting the *P. falciparum* antigen histidine-rich protein-2 (PfHRP2) scoring slightly better than *P. falciparum*-lactate dehydrogenase (PfpLDH)-detecting RDTs. Some detect one or more of the other three species of malaria which infect humans by detecting various other antigens.

RDTs for the fifth human malaria, *Plasmodium knowlesi*, are currently under development. *P. knowlesi* infections can result in a high parasitemia causing severe malaria in many infected individuals. If detected early and treated with appropriate drugs, these patients demonstrate significant clinical improvement. Unfortunately, microscopic methods usually misidentify *P. knowlesi* as the less pathogenic *P. malariae*, leading to inadequate therapy and adverse clinical outcomes. The rapid immunochromatographic card tests have a very low sensitivity in diagnosing knowlesi malaria and can erroneously report *P. knowlesi* as other plasmodia and vice versa (52). With RDTs, patients with *P. knowlesi* could be misdiagnosed as *P. falciparum* with OptiMAL-IT, as *P. vivax* with Paramax-3, and more correctly as non-*P. vivax*/non-*P. falciparum* with BinaxNOW Malaria. There is a need for a sensitive and specific RDT for malaria diagnosis in settings where *P. knowlesi* infections predominate (53).

RDTs are available in three different formats. The simplest form is a dipstick, which is placed in wells containing blood and/or buffer. The nitrocellulose strip may be placed in a cassette, or the third option is to place the strip on a card. Although the cassettes and cards are more expensive, they are considered the easiest to use. As with any diagnostic test system, it is critical that directions be followed and interpretive criteria be thoroughly understood by the user. Also, when diagnosing malaria, patient signs and symptoms should always be considered in addition to the RDT result.

However, these tests do have limitations, including persistence of the PfHRP2 antigen, cross-reactions of *P. falciparum* with the non-falciparum test line and vice versa, and (rare) false-positive reactions due to other infectious agents or immunological factors. False-negative results occur in the case of low parasite densities, which may be a problem with immunologically naive patients who tend to become symptomatic very early with parasitemias as low as <0.002% or lower (100/µl). As an example, the BinaxNOW (Alere, Inc., Waltham, MA) (the only FDA-approved RDT in the United States at the time of this writing) has a maximum sensitivity at 0.1% (5,000/µl). The same test may achieve a high sensitivity in a population in which all infected people have high parasite density (e.g., above 10,000/µl), but achieve low sensitivity in areas where parasite densities are frequently below 200/µl. RDTs are a valuable adjunct to (but not a replacement for) microscopy for the diagnosis of malaria in the returned traveler. In malaria-endemic settings, many of which may be in remote areas, potential problems may include limited temperature control, poor resupply options, and limited training for health workers.

Sensitivity remains a problem, particularly for nonimmune populations. Parasite densities of >100 parasites/µl (0.002% parasitemia) should be detected and are reasonable targets to expect from dipsticks for *P. falciparum* diagnosis. However, this level of sensitivity is at the lower end of the capability of most devices using capture methods for HRP-2 or pLDH. This level of sensitivity is probably as good as clinical laboratory staff in nonspecialized laboratories with limited exposure to malaria cases could expect to provide using microscopy diagnosis. One of the potential benefits would be for inexperienced evening staff personnel, for whom the dipstick identification of a life-threatening parasitemia with *P. falciparum* could prevent a missed infection. However, a negative test could not be accepted and would require confirmation by microscopic examination of both thick and thin blood films for the detection of parasitemia below the present threshold of detection by these rapid tests. Also, there are rare false positives for patients with certain rheumatologic disorders; this is noted in the package insert and has been confirmed by users in this patient population.

Toxoplasmosis

Toxoplasma gondii is capable of infecting a wide range of hosts, including mammals, birds, and reptiles. The first recognized case of human toxoplasmosis was described by Janko, an ophthalmologist, in 1923. The infection can be contracted by ingestion of oocysts from fecal material (animals in the cat family, *Felidae*), ingestion of tissue cysts from raw or inadequately cooked meat, organ transplantation, transfusions, or transplacental transmission. Human infection occurs primarily through the ingestion of raw or undercooked infected meat.

Infection or colonization by *T. gondii* appears to be common in most parts of the world, particularly where cats are found. In the United States, approximately 30% of adults have been exposed to toxoplasmosis; however, the vast majority of these adults did not have recognizable illness.

Congenitally acquired toxoplasmosis can result in serious and debilitating sequelae, including stillbirths, defects seen at birth, and infections in infants who are frequently asymptomatic at birth. In the latter cases, sequelae of congenital infection may arise later in life, most commonly between the first and third decades (54). The incidence of congenital toxoplasmosis is virtually unknown and may be greatly underreported. The clinical severity of congenital toxoplasmosis varies considerably with the trimester of pregnancy when the maternal infection was acquired. Infections contracted during the third trimester result in a large number of congenital infections; however, most infants show no sign of disease. Although infections acquired by the mother in the first trimester result in a smaller number of infected infants, sequelae are the most severe, including a number of stillbirths. Recent evidence suggests that most infants with subclinical infection at birth will develop signs or symptoms of disease (chorioretinitis) as they approach adulthood.

The diagnosis of acute *Toxoplasma* infection can be established by the following: isolation of tachyzoites from blood or body fluids; demonstration of tachyzoites in cytologic preparations or tissue sections; lymph node histologic testing; demonstration of cysts in such tissues as the placenta or in the fetus or neonate; antigen detection; or serologic test results. In older children or adults, the isolation of *T. gondii* from tissues may reflect only the presence of cysts. However, depending on the clinical presentation, the isolation of the organism from lymph node tissue may reflect the presence of tachyzoites.

Antibody Detection. Since isolation of the parasite is not practical for most laboratories, serologic tests are routinely used for diagnosis (Table 33.6). Properly interpreted serologic test results provide excellent supportive evidence for the clinician. Different serologic tests often measure different antibodies that demonstrate distinct patterns of rise and fall with time after infection. A combination of serologic tests is frequently required to establish whether an individual has been infected in the distant past or has been recently infected. An IgM test is used to help determine whether a patient has been infected recently or in the dis-

tant past. Despite the wide distribution of commercial test kits to measure IgM antibodies, these kits often have low specificity and the reported results are frequently misinterpreted. In addition, IgM antibodies can persist for months to more than 1 year. Thus, due to the frequency of misinterpretation of a positive IgM test result, confirmatory testing should be performed.

The Toxoplasma Serology Laboratory of the Palo Alto Medical Foundation Research Institute, Palo Alto, CA (TSL-PAMFRI) offers confirmatory serologic and PCR testing and methods for isolation of the organism. In addition, their medical consultants (Jose G. Montoya, M.D., Jack S. Remington, M.D., and Despina Contopoulos-Ioannidis, M.D.) are available for interpretation of test results and advice on management of patients. This laboratory provides a toxoplasma serological profile (TSP) panel of tests for confirmatory testing. The TSP panel comprises the Sabin-Feldman Dye Test, double sandwich IgM ELISA, IgA ELISA, IgE ELISA, and AC/HS (differential agglutination) test. The TSP has been used successfully to determine whether serological test results are more likely consistent with infection acquired in the recent or more distant past. Extensive test explanations and interpretation can be found in Table 33.7 (55).

Properly interpreted serologic test results provide excellent supportive evidence for the clinician. Classically, the detection of *Toxoplasma* infections has been based on the detection of IgG and IgM antibodies. Diagnostic reagent comparisons indicate that most are comparable in the detection of anti-*Toxoplasma* IgG but vary considerably in the detection of IgM antibodies. It has been shown that specific IgA antibodies are extremely useful in the diagnosis of congenital and acute toxoplasmosis (56). Another test for detecting acute infection involves the antigen binding avidity of IgG antibodies (57).

Individuals should be initially tested for the presence of *Toxoplasma*-specific antibodies to determine their immune system status. A positive IgG titer indicates infection at some point in time. Women who have a positive IgG titer before pregnancy have never been found to transmit *Toxoplasma* infection to the fetus, regardless of the antibody titer. Women who have no demonstrable antibody must be considered at risk for infection. Because the diagnosis of acute toxoplasmosis is usually based on serologic test results and is frequently considered late in the patient's clinical course, serologic titers may have already reached their peak. In these cases, examination of paired sera would be of little benefit and a single high titer may not indicate recent infection, since titers can remain high for years.

TABLE 33.7 *Toxoplasma gondii* serological profile panel (TSP) used in the Toxoplasma Serology Laboratory of the Palo Alto Medical Foundation Research Institute[a]

Test	Explanation	Comments
IgG antibodies, DT	Measured by Sabin-Feldman Dye Test (DT). The DT is a sensitive and specific neutralization test in which live organisms are lysed in the presence of complement and the patient's IgG *T. gondii*-specific antibody. IgG antibodies usually appear within 1 to 2 weeks of the infection, peak within 1 to 2 months, fall at variable rates, and usually persist for life. The titer does not correlate with the severity of illness.	A positive DT indicates the patient has been exposed to *Toxoplasma*. A negative DT essentially rules out prior exposure to *Toxoplasma* (unless the patient is hypogammaglobulinemic). However, in a small number of patients, IgG antibodies might not be detected within 2 to 3 weeks after the initial exposure to the parasite. Also, rare cases of chorioretinitis and toxoplasmic encephalitis in immunocompromised patients have been documented in patients negative for *T. gondii*-specific IgG antibodies.
AC/HS	The differential agglutination test (also known as the "AC/HS test") uses two antigen preparations that express antigenic determinants found early following acute infection (AC antigen) or in the later stages of infection (HS).	Ratios of titers using AC versus HS antigens are interpreted as acute, equivocal, nonacute patterns of reactivity or nonreactive. The acute pattern may persist for 1 or more years following infection. This test has proved useful in helping differentiate acute from chronic infections but is best used in combination with a panel of other tests.
Avidity	The affinity of specific IgG antibodies is initially low after primary antigenic challenge and increases during subsequent weeks and months. Protein-denaturing reagents including urea are used to dissociate the antibody-antigen complex. The avidity result is determined using the ratios of antibody titration curves of urea-treated and untreated serum.	The avidity test is used as an additional confirmatory diagnostic tool in the TSP for those patients with a positive and/or equivocal IgM test or acute and/or equivocal pattern in the AC/HS test. It is important to remember that avidity testing is a confirmatory test and not the ultimate test for decision-making in pregnant women. Its highest value is observed when laboratory test results reveal high IgG avidity antibodies and the serum is obtained during the time window of exclusion of acute infection for a particular method (i.e., 12 weeks for the Labsystems method, 16 weeks for the VIDAS-bioMérieux method). Low or equivocal IgG avidity antibody results should not be interpreted as diagnostic of recently acquired infection. These low or equivocal avidity antibodies can persist for months to 1 year or longer.
IgM antibodies	Measured by the "double-sandwich" or "immuno-capture" IgM-ELISA method. This method avoids false-positive results due to the presence of rheumatoid factor and antinuclear antibodies.	In most cases, these titers become negative within a few months. However, positive IgM *T. gondii*-specific titers can be observed during the chronic stage of the infection and can persist as long as 12 years after the acute infection. Persistence of these IgM antibodies does not appear to have any clinical relevance, and these patients should be considered chronically infected. IgM results obtained at non-reference laboratories should be confirmed at a *Toxoplasma* reference laboratory; interpretation per confirmatory testing would be interpreted as (i) a recently acquired infection, (ii) an infection acquired in the distant past, or (iii) a false-positive result.
IgA antibodies	IgA antibodies may be detected in sera of acutely infected adults and congenitally infected infants using ELISA or ISAGA methods[b]	IgA antibodies may persist for many months to more than 1 year. For this reason they are not helpful for diagnosis of acute infection in the adult. However, the increased sensitivity of IgA assays over IgM assays for diagnosis of congenital toxoplasmosis represents an advance in diagnosis in the fetus and newborn. In a number of newborns with congenital toxoplasmosis and negative IgM antibodies, the serological diagnosis has been established by the presence of IgA and IgG antibodies.
IgE antibodies	IgE antibodies are detectable by ELISA in sera of acutely infected adults, congenitally infected infants, and children with congenital toxoplasmic chorioretinitis.	The duration of IgE seropositivity is less than with IgM or IgA antibodies and hence appears useful as an adjunctive method for identifying recently acquired infections.
PCR	PCR is used to detect *T. gondii* DNA in body fluids and tissues. It has been successfully used to diagnose congenital, ocular, cerebral, and disseminated toxoplasmosis. PCR performed on amniotic fluid has revolutionized the diagnosis of fetal *T. gondii* infection by enabling an early diagnosis to be made, thereby avoiding the use of more invasive procedures on the fetus.	PCR has allowed detection of *T. gondii* DNA in brain tissue, CSF, vitreous and aqueous fluid, bronchoalveolar lavage fluid, urine, amniotic fluid, and peripheral blood.

---

[a] This testing panel has been clinically relevant in cases of toxoplasmic lymphadenitis, myocarditis, polymyositis, and chorioretinitis and during pregnancy. In cases where sera demonstrate positive IgG and IgM tests, the ability of this panel to differentiate between recently acquired and chronic infections is much better than any single serological test. Information adapted from: *Toxoplasma Serology Laboratory: A Guide for Clinicians* (Palo Alto Medical Foundation; http://www.pamf.org/serology/clinicianguide.html, accessed 20 June 2014). Links to serologic specimens, PCR specimen requirements, and PCR instructions can be found at this site.

[b] ISAGA, immunosorbent agglutination assay.

In acute and congenital toxoplasmosis, IgA and IgM antibodies are the first to be detected. Normally, IgM and IgA antibodies do not cross the placental barrier, and these antibodies have been used as the hallmark of congenital infection. The IgA and IgM titers continue to rise during the first few weeks of infection and may remain positive for a year or more (56). It is possible that the IgA and IgM titers will decrease to undetectable levels by 5 or 6 weeks postinfection; however, this is not always the case, and high levels may indicate infection within the past 3 to 5 months. In some cases, IgM antibodies may be detected by EIA for months to years after acute acquired infection. IgM antibody methods have given both false-positive and false-negative results because of the presence of rheumatoid factor, blocking antibody, and the induction of fetal IgM antibodies against maternal immunoglobulin. The IgM test should be performed using a method such as the IgM capture ELISA to minimize nonspecific reactions (2). It is important to remember that all IgM-positive results should be verified by a reference laboratory such as the CDC or the Toxoplasma Serology Laboratory of the Palo Alto Medical Foundation Research Institute (Palo Alto, CA).

Generally, the demonstration of either IgA or IgM serum antibody is considered diagnostic; however, the use of cord serum is unreliable because of the possible presence of maternal antibody. Both maternal and infant sera should be monitored at the same time. If both sera are positive, the infant's serum should be retested within 1 to 2 weeks. An infant IgA or IgM titer which is stable or continues to rise is diagnostic of infection. Immunocompromised patients and those with ocular toxoplasmosis may have no demonstrable antibody response. AIDS patients with active toxoplasmosis, including central nervous system disease, generally have no IgM antibodies and a low to moderate level of (or occasionally no) IgG antibodies (58). Early treatment of the infection may considerably delay or reduce the normal host immune response.

Antigen Detection. Tests for the detection of circulating antigen have been used for the diagnosis of infection but have not been widely accepted (56, 59). Studies indicate that detection of some low-molecular-weight antigens is diagnostic of reactivated toxoplasmosis (60). These antigens can be detected even with normal dye test titers, and their detection improves the diagnosis of reactivated disease. They may be the result of the release of bradyzoites from ruptured tissue cysts. Because of the difficulties associated with reliable serologic methods for the diagnosis of toxoplasmosis, other methods such as molecular diagnostics have been used for diagnosis. PCR assays are available primarily in specialized research centers (56). PCR is a rapid and specific means of detecting the parasite in infected individuals who have failed to mount an immune response and allows for the infection to be detected much earlier in gestation.

A specific antibody and Western blot analyses have been used to demonstrate the presence of a highly reactive antigen of 36 kDa, not only in the extract of *T. gondii* tachyzoites but also in selected sera of women with confirmed laboratory and clinical signs of recent toxoplasmosis. The 36-kDa antigen was purified from *T. gondii* tachyzoites and human serum by using electroelution from preparative polyacrylamide gels. An ELISA format for the detection of target *Toxoplasma* antigen (TAg-ELISA) in human serum samples has recently been developed. The TAg-ELISA detected the target antigen in 88% of sera of acutely infected women, with 91% specificity among sera from noninfected women. The detection of 36-kDa *Toxoplasma* circulating antigen in human sera appears to be a promising alternative approach for the laboratory diagnosis of active *T. gondii* infection (61).

Trichomoniasis

The diagnosis of *Trichomonas vaginalis*, a sexually transmitted disease, relies primarily on direct microscopic examinations of wet mounts. Trophozoites can be detected in vaginal secretions, urethral specimens, or spun urine. The sensitivity of the direct wet mounts is low (50 to 85%) and can be improved by culture of the organism. DFA and LA reagents are now commercially available, and both can be used on vaginal swab specimens or fluids (62). The automated Affirm VP Microbial Identification Test system is also available and is being used in physician office settings, clinics, and routine clinical laboratories (62) (see Appendix 8). Using oligonucleotide probes, the system can detect *T. vaginalis* and *Gardnerella vaginalis* from a single vaginal swab. Sensitivity has been reported as 100% compared with wet preparation examination but only 80% compared with culture. Although there are still limitations for specimen storage conditions and times, one of the benefits is certainly flexibility for laboratories serving large outpatient populations.

Helminth Infections

Cysticercosis

The diagnosis of cysticercosis usually depends on surgical removal of the parasite and microscopic examination for the presence of suckers and hooks on the scolex. Multiple larvae are frequently present, and the presence of cysticerci in the subcutaneous or muscle tissues indicates that the brain is probably also involved. The calcified larvae can be readily seen on X-ray examination. Computed tomography (CT) scans or magnetic resonance imaging (MRI) techniques may reveal the presence of lesions in the brain. Although neurocysticercosis may be suspected, particularly in a patient living in an area of endemicity, the multiple neurologic syndromes and the various clinical presentations make it difficult to confirm the diagnosis, even with CT or MRI techniques. Human cysticercosis caused by *Taenia solium* is an important public health problem in developing nations and is often the leading cause of epileptic symptoms.

Antibody Detection. Serologic tests used for diagnostic purposes include CF, IHA, IFA, ELISA, immunoblotting, ID, and radioimmunoassay (63). IgG is the predominant immunoglobin detected in patients with cysticercosis; IgA, IgE, and IgM antibodies are of little value in diagnosis and cannot be correlated with the patient's clinical condition. Serodiagnosis of cysticercosis has been a problem because of cross-reactions occurring in patients with coenurus, *Echinococcus*, filaria, and *Taenia saginata* infections.

The CDC enzyme-linked immunoelectrotransfer blot (EITB) using purified *T. solium* antigens has been acknowledged by the World Health Organization and the Pan American Health Organization as the immunodiagnostic test of choice for the diagnosis of cysticercosis (64). It is 100% specific and has an extremely high sensitivity. The test employs purified glycoproteins, making it more sensitive than ELISA, and has eliminated the problems with nonspecificity noted above. Both serum and CSF can be used as diagnostic specimens. The test may be more sensitive with serum than CSF; therefore, there is no need to obtain CSF. For patients with multiple cysts (more than two cysticerci), the test has a sensitivity of 98%. Patients with multiple calcified cysts had a seropositivity of 82%, whereas patients with a single parenchymal cyst had a seropositivity of 50 to 70%. Several private laboratories now offer this test, which was previously available only at CDC.

Several immunoassay kits are also commercially available (Table 33.2). The clinical tests for the diagnosis of cysticercosis cannot be used to distinguish between present and past infections, nor can they be used to monitor the progress of therapy.

The assay of choice for serologic detection of cysticercosis in humans and pigs is EITB, a Western blot assay that relies on the use of chromatography affinity-purified glycoproteins derived from *T. solium* metacestodes. This test facilitates the diagnosis of lesions (usually intracranial) that are compatible with *T. solium* cysts by CT or MRI scans. Although the gold standard test is a tissue biopsy, this procedure is seldom used in the diagnosis of cysticercosis. The sensitivity of the immunoblot depends upon the number and vitality of the cysts. Sensitivity is estimated to be 98% in biopsy-proven cases of neurocysticercosis with two or more cysts. Sensitivity decreases in cases with a single enhancing cyst or calcified cysts (range 28% to 72%). In patients with only subcutaneous cysts, the sensitivity is <50%. The specificity of the test is thought to be 100% and no cross-reactivity is known. Both serum and CSF may be tested, but the highest sensitivity can be achieved in serum.

EITB antigens have now been reproduced in synthetic forms. Four chemically synthesized antigens were assayed individually using ELISA and Western blotting for immunoreactivity against sera from clinically defined neurocysticercosis patients. The sensitivity and specificity of all four antigens using the ELISA format did not meet the standards set by the lentil-lectin-purified glycoproteins (LLGP) EITB, while the results of the Western blot format were comparable to those of the LLGP EITB (65).

Antigen Detection. An ELISA for the detection of antigen secreted by viable *T. solium* metacestodes has been used on pre- and posttreatment CSF samples from Peruvian patients with neurocysticercosis demonstrated by CT and EITB; the sensitivity was 86% (66). There was no difference between antigen levels in CSF taken before or 14 days after therapy. There was a significant positive correlation between antigen levels, the number of live cysts detected by CT, and the EITB results. In contrast, there was a negative correlation with the number of enhancing lesions by CT, supporting the hypothesis that enhancing lesions correspond to a late, dead stage of the parasite. This test approach using antigen specific for viable parasites has great clinical relevance, not only for providing information on the viability of the organisms but also for understanding the pathogenesis of neurocysticercosis before and after therapy.

Antigens and antibodies in sera from humans with epilepsy or taeniasis in an area of Mexico where *T. solium* cysticercosis is endemic have also been evaluated (67). Parasite-specific antigens and antibodies were more common among patients with epilepsy and taeniasis than among the controls. Antigens seemed to be associated with late-onset epilepsy, while the antibodies were associated with subcutaneous nodules. The sensitivities of both tests were low in terms of disease detection; however, the specificity and the positive predictive value of the antigen capture assay were high when used on sera from patients with late-onset epilepsy. Since late-onset epilepsy and neurocysticercosis are associated in areas of endemic infection, antigen capture assays may provide a reliable method of detecting active cases of neurocysticercosis.

Hydatid Disease

In an area of endemic infection, exposure to sheepdogs, the presence of an enlarged liver, the presence of a palpable mass in the right upper quadrant of the abdomen, expectoration of a salty-tasting fluid with hemoptysis, and a round lesion on chest radiographs all support the presumptive diagnosis of hydatid disease in either the liver or lungs. Hydatid cysts in the liver may be confused with congenital liver cysts, amebic abscess, or hepatic tumors. Pulmonary symptoms may be confused with tuberculosis. Hydatid cysts should be considered in patients with abdominal masses for which there is no clearly defined diagnosis. Many asymptomatic cysts are first discovered after radiologic studies.

Antibody Detection. Immunodiagnostic tests have been very helpful in confirming the diagnosis of echinococcosis caused by *Echinococcus granulosus* (cystic disease) or *E. multilocularis* (alveolar disease). Serum antibodies to *Echinococcus* spp. have been detected by IHA, IFA, ELISA, CF, LA, immunoelectrophoresis, immunoblotting, and ID. The immune response depends on the location and viability of the cyst. Individuals harboring calcified, senescent, or dead cysts often have a negative serologic test result. Liver cysts produce a greater serologic response in the patient than do hyaline or lung cysts, and up to 50% of patients with lung cysts are serologically negative. Cysts in the brain and spleen are also associated with a decreased immune response in the host.

A dipstick assay for the serodiagnosis of human hydatidosis using camel hydatid cyst fluid was compared with EITB and Falcon assay screening test-ELISA (FAST-ELISA). For the diagnosis of hydatidosis, the sensitivity, specificity, and diagnostic accuracy of the dipstick assay and EITB were 100, 91.4, and 95.1%, while those of FAST-ELISA were 96.2, 100, and 98.4%, respectively. Since the dipstick assay is easy to perform, has a visually interpreted result within 15 min, and is both sensitive and specific, it could be an acceptable alternative for use in clinical laboratories lacking specialized equipment and the technological expertise needed for EITB and FAST-ELISA (68).

Serologic cross-reactions have been noted in low titers in patients with other parasitic diseases, liver cirrhosis, and collagen diseases (1). A test involving a selected antigen called arc-5 or the 8-kDa antigen has been developed for the specific diagnosis of *Echinococcus* infections. It is recommended that serum be screened by either ELISA or IHA and all positive reactions be confirmed by immunoblotting (2). False-positive reactions with the arc-5 antigen can occur with cysticercosis; however, use of the 8-kDa antigen in the immunoblot assay eliminates this cross-reactivity. Immunoblotting using the 8-kDa antigen provides 99% discrimination between seropositive preoperative cystic hydatid disease cases and cross-reactive noncestode parasitic infections or malignancies.

Cross-reactivity can occur between species. The use of purified *E. multilocularis* antigens with either ELISA or immunoblotting methods has been helpful in differentiating infections caused by the two species (69, 70). Immunoblot tests have been used to monitor the therapy of patients, whereas IHA and ELISA may continue to give positive results for years. Tests for the detection of circulating antigen have been used for diagnosis of infection, but they are not readily available.

Currently EIA with a confirmatory immunoblot is being used. This test plays an important role in the evaluation of suspected hydatid cysts (e.g., liver, lung). Given that aspiration of such cysts is contraindicated, the combination of positive serology and typical CT or MRI appearance of the cyst (e.g., internal septations, daughter cysts, lily pad) is often sufficient to make a secure diagnosis. The sensitivity of the EIA test is high but its specificity is relatively low, with 10–15% false-positive results due to cross-reactions in a wide variety of helminth infections (e.g., cysticercosis) and noninfectious conditions (e.g., cancer, pregnancy, autoimmune diseases). Furthermore, the high sensitivity refers to long-standing hepatic disease only. *E. granulosus* titers may be false negative in several situations; small cysts (e.g., early after infection), intact cysts (i.e., no leakage of the immunogenic cyst fluid), cysts in extrahepatic locations, and heavily calcified cysts (e.g., nonviable). The results of this test should be interpreted with additional caution when an organism other than “classic” *E. granulosus* is suspected on the basis of clinical or epidemiological information (e.g., Arctic *E. granulosus*).

Patients with alveolar hydatid disease are usually serology positive when heterologous *E. granulosus* or homologous *E. multilocularis* antigens are used; crude antigens tend to give nonspecific reactions in alveolar disease, as seen with cystic disease. Immunoaffinity-purified *E. multilocularis* antigens (Em2) used in an EIA method give positive results in >95% of cases of alveolar disease. Tests using Em2 are also more useful for monitoring postoperative conditions than for monitoring posttherapy effectiveness.

Antigen Detection. Efforts to standardize and evaluate the LA test as a simple test for the detection of circulating hydatid antigen in serum are under way. The latex particles were sensitized with hyperimmune hydatid antiserum raised in rabbits. The LA test showed a sensitivity of 72%, a specificity of 98%, a positive predictive value of 93%, and a negative predictive value of 91%. This is the first report of use of the LA test for the detection of hydatid antigen in serum in the diagnosis of cystic echinococcosis (71).

An ELISA using polyclonal antibodies against 24-kDa urinary hydatid protein was moderately sensitive in detecting hydatid antigen in serum and urine. Hence, polyclonal antibodies to 24-kDa urinary hydatid antigen can be used as an alternative source of antibody to detect hydatid antigen in serum, urine, and cyst fluid (72).

Fascioliasis

In *Fasciola hepatica* infections, metacercarial larvae do not cause significant pathologic damage until they begin to migrate through the liver parenchyma. The amount of damage depends on the worm burden of the host. Hyperplasia of the bile ducts occurs, possibly as a result of toxic substances produced by the larvae. Symptoms associated with this migratory phase have included fever, epigastric and right upper quadrant pain, and urticaria, although no eggs are found in the stool until the worms mature, which takes 8 weeks; some patients experience no symptoms.

Once the worms have established themselves in the bile ducts and matured, they cause considerable damage from mechanical irritation and metabolic by-products as well as obstruction. The degree of pathology depends on the number of flukes penetrating the liver. The infection produces hyperplasia of the biliary epithelium and duct fibrosis with portal or total biliary obstruction. The gallbladder undergoes similar pathologic changes and may even harbor adult worms. Adult worms may reinvade the liver parenchyma, causing abscesses.

Multiple stool examinations may be needed to detect light infections. Eggs may be detected in the stool of individuals who have eaten *F. hepatica*-infected liver, thereby yielding an erroneous laboratory result.

Antibody Detection. Serologic diagnosis using *F. hepatica* excretory-secretory antigens has been successfully used in areas of endemicity to detect patient antibodies. This approach includes both ELISA and EITB testing. Antibodies may be detected within 2 to 4 weeks after infection. Sensitivity for the FAST-ELISA was reported to be 95%, while sensitivity for the immunoblot assay using 12-, 17-, and 63-kDa antigens was 100%. However, there does appear to be some cross-reactivity with patients who have schistosomiasis. Serologic test results can be used to monitor treated patients to ensure successful therapy, after which antibody levels drop to normal within 6 to 12 months. Serologic tests are the tests of choice for the diagnosis of acute and chronic fascioliasis when few eggs can be found in the stool or when large populations are being screened. However, the immunodiagnosis of fascioliasis, in Central European regions of low endemicity, has remained a major challenge, and routine diagnostic laboratories are struggling with the selection of a suitable and reliable test.

An ELISA has been developed based on the detection of serum IgG4 antibodies reactive with *F. hepatica* cathepsin L1 (CL1). In an area of high prevalence of fascioliasis, a highly statistically significant correlation was seen when the recombinant and native proteins were used. The assays showed that 38 (59%) of the individuals tested were seropositive while only 26 were positive for *F. hepatica* eggs in the stool. All patients with egg-negative stools were also serologically negative. Also, there was no cross-reactivity with sera from patients with schistosomiasis, cysticercosis, hydatidosis, or Chagas' disease. This study indicates that recombinant CL1 shows excellent potential for use in the development of a standardized assay for the diagnosis of human fascioliasis (73).

In another study of ELISAs using recombinant saposin-like protein 2 and recombinant cathepsin L-1 from *F. hepatica*, results demonstrated excellent performance of re-cSAP2 in relation to specificity (99%), sensitivity (87%), and cross-reactivity (no cross-reactivity with neurocysticercosis and filariasis sera). Based on these results, use of this test in the routine clinical laboratory for the diagnosis of human fascioliasis is warranted (74).

Immunoblotting studies showed that an 8-kDa protein reacts with sera from humans with fascioliasis but not sera from humans with other trematode infections. This result suggests that the 8-kDa protein of *F. hepatica* is one of the diagnostic antigens in human fascioliasis without cross-reaction and may be very useful in the diagnosis of fascioliasis (75).

Antigen Detection. The detection of coproantigens by means of an ES78 sandwich ELISA has been used; coproantigens were detected in all patients with patent infections. The data indicate that this approach is more sensitive than stool examinations for eggs, particularly in early infections (76). A new lateral flow immunoassay also appears to have potential as a point-of-care diagnostic test for the diagnosis of fascioliasis (77).

Filariasis

Lymphatic Filariasis

A wide variety of serologic tests have been used for diagnostic and epidemiologic purposes in cases of human filariasis. Except for use in patients not native to the area of endemicity, immunodiagnostic tests are of limited value. Current tests lack both sensitivity and specificity, and most people from the region of endemicity have a positive serologic response. This response may be due to exposure to nonhuman filarial antigens from infected mosquitoes, and filarial antigens may cross-react with antibodies to other parasitic diseases.

Antibody Detection. The immune response of the filaria-specific IgG4 is considerably increased in patients with active filarial infections. The detection of IgG4 antibodies also reduces the cross-reactivity of nonfilarial antibodies.

IgG2 production appears to be increased in patients with elephantiasis. Studies also suggest that specific antisheath antibodies are associated with an immunologic resistance mechanism that in the endemic community is expressed with highest prevalence in young individuals before the development of patent microfilaremia. However, antibody tests cannot differentiate past from present infection, nor do they show any correlation between antibodies and worm burden.

In the simple and rapid Brugia Rapid (BR) test, an immunochromatographic dipstick is used to detect IgG4 antibodies that are reactive with a recombinant *Brugia malayi* antigen. When sera from 109 individuals with *Brugia* microfilaremias (12 infected with *B. malayi* and 97 infected with *B. timori*) were investigated using the BR test, all were found to be positive. In contrast, all of the 150 sera from individuals with *Onchocerca volvulus* or *Mansonella* infections were found to be negative in BR tests. Some cross-reactions were observed with sera from individuals infected with *Wuchereria bancrofti* (3 of 12 tests positive) and *Dirofilaria* (1 of 9 tests positive) (78).

A rapid-format, simple, and qualitative flowthrough immunofiltration test has been developed for the identification of total IgG antibodies to recombinant filarial antigen WbSXP-1. This test system employs colloidal gold-protein A reagent as the antibody capture reagent. The sensitivity was 90.8% and 91.4% with brugian and bancroftian microfilaremic patients, respectively. The test showed minimum reactivity with *Loa loa* microfilaria-positive sera and no reactivity with *Onchocerca*-positive sera. The test was nonreactive with samples from individuals suffering from other parasitic diseases including schistosomiasis, soil-transmitted helminth infections, and protozoan infections, confirming the potential of this test as a diagnostic tool for both brugian and bancroftian lymphatic filariasis (79).

Some reference laboratories are now using an EIA for antibody detection. Indications for use include several clinical syndromes suggesting a filarial etiology, and screening asymptomatic individuals whose sera and geographic origins or travel make a filarial infection possible. Settings in which testing could be appropriate include generalized itchiness (onchocerciasis), lymphangitis (*W. bancrofti*, *B. malayi*), eosinophilic lung disease (*W. bancrofti*), or a history of intermittent swellings (*L. loa*). This test is of little use in the diagnosis of chronic lymphadema (elephantiasis), hydrocele, and chylurea, all of which typically complicate "burned out" filarial disease. The gold standard for diagnosis of filarial disease remains visualization of adult worms (e.g. *L. loa* eye worm, visualization of mobile worms using ultrasound), or microfilaria (e.g., skin snip). A positive titer (≥1:128) indicates a filaria infection but gives no information with regard to disease state (e.g., acute, chronic, cured). Virtually all residents of filariasis-endemic areas are antibody positive. Anti-filaria antibodies may persist for years after infection. Therefore a single test result must be interpreted with caution when prior infection is possible.

Antigen Detection. Because of the lack of sensitivity in direct-detection methods and problems with obtaining blood specimens within correct time frames, detection of circulating antigens has been used diagnostically. Antigen detection has also been used to monitor therapy. Many of these methods are not yet standardized and are not substitutes for direct-detection methods. Most are not sensitive enough to detect amicrofilaremic individuals who have clinical filariasis.

PCR assays will be a very useful diagnostic tool because they can discriminate between past and present infection and can be used to monitor therapy. In a preliminary evaluation of the diagnostic capability of PCR with diurnally collected sputum from bancroftian filariasis patients, the data were excellent; this approach appears to have excellent potential (80). New approaches for antigen detection also include (i) the ICT card test for serum specimens, (ii) the TropBio ELISA for serum specimens, and (iii) the TropBio ELISA for filter paper specimens; data from all three methods were very promising for their use as diagnostic tools in bancroftian filariasis (81, 82).

Onchocerciasis

The prepatent period of onchocerciasis in humans is 3 to 15 months. Light infections may cause no symptoms, and worms may be free in the tissue; however, in heavy infections, major disease manifestations include dermatitis, onchocercomas (subcutaneous nodules containing adult worms), lymphadenitis, and blindness. Even though there is an inflammatory reaction that causes the formation of a fibrotic capsule (onchocercoma) around the adult worm, the main pathology appears to be directed against the microfilariae.

Antibody Detection. Recombinant antigens for serologic diagnosis can help overcome the problems associated with poor sensitivity and specificity, particularly in areas where other human filarial infections overlap with those caused by *Onchocerca volvulus*. A cocktail of recombinant *O. volvulus* antigens for serologic diagnosis with the potential to predict the endemicity of onchocerciasis infection has been developed (83). When a sentinel population of 5- to 15-year-old individuals was used to compare communities, the serologic index was sufficiently sensitive to measure the changes in endemicity that would be required for control programs. However, serologic testing cannot distinguish between current and past infection and tends to be more important in monitoring specific groups.

It has also been shown that tests based on IgE detection are more specific than those based on IgG detection. However, current tests still lack sensitivity and specificity, and the results do not correlate with past or present infection or with parasite burden.

Four recombinant *O. volvulus* antigens (Ov-FAR-1, Ov-API-1, Ov-MSA-1, and Ov-CPI-1) were tested by luciferase immunoprecipitation systems (LIPS) on a large cohort of blinded sera comprising both uninfected controls and patients with a proven parasitic infection including *O. volvulus*, *W. bancrofti*, *L. loa*, *S. stercoralis*, and other potentially cross-reactive infections. Antibody responses to the four different *O. volvulus* antigens produced unequivocal differentiation between infected and uninfected control sera, with 100% sensitivity and 100% specificity. The multiantigen LIPS assay can be used as a rapid, high-throughput, and specific tool to diagnose individual *O. volvulus* infections, as a sensitive and potentially point-of-care method for early detection of recrudescent infections in areas under control, and for mapping new areas of transmission of *O. volvulus* infection (84).

Antigen Detection. Studies have been reported using recombinant proteins and a dipstick immunobinding assay (DSIA) for the detection of ocular microfilariae, a transblot immunobinding assay (TADA) for the detection of skin microfilariae, and a dot blot immunobinding assay (DIA-BA) for the detection of urinary microfilariae (85). Sensitivities were 100% for DSIA, 82.5% for TADA used on samples of tears, 97% for TADA used on dermal fluids (skin snip), and 96% for DIA used on urine samples.

A recent report discussed the development and evaluation of a DIA-BA based on the biotin-avidin binding system for the detection of *O. volvulus*-specific antigens in body fluids (86). The biotinylated probes were used to detect *O. volvulus*-specific antigens initially blotted onto a nitrocellulose membrane. The smallest amount of blotted antigens detectable by the new test is 0.5, 1, 1, and 2 ng in urine, dermal fluid, tears, and serum samples, respectively. The test was 100% sensitive when used with urine and only 54.76% when used with serum from skin-snip-positive subjects. The specificity of the test was 100%, while the dermal fluid specificity was 97.5%. Also, there was a positive correlation between the color intensities on the blot and the skin microfilaria loads of the individuals. The DIA-BA test could be very useful for mass diagnosis of prepatent, low-level, and high-level infections due to *O. volvulus* (86).

Paragonimiasis

Humans become infected with *Paragonimus* spp. by ingesting uncooked crabs or crayfish containing metacercariae. The metacercariae excyst in the duodenum and migrate through the intestinal wall into the abdominal cavity. The larvae migrate around or through the diaphragm into the pleural cavity and the lungs. They mature to adults in the vicinity of the bronchioles, where they discharge their eggs into the bronchial secretions. Individuals with symptoms of chronic cough, vague chest pains, and hemoptysis who have resided in an area where infections are endemic and have a history of eating raw crayfish or crabs should be suspected of having paragonimiasis. *Paragonimus* eggs can be detected in sputum and in the stool, and concomitant examinations should be performed to improve the overall detection rate. In many individuals in whom the infection is eventually confirmed, small numbers of eggs are present intermittently in the sputum and feces. For patients with light infections, up to seven sputum examinations have been recommended. Frequently, pulmonary paragonimiasis is misdiagnosed as pulmonary tuberculosis. The Ziehl-Neelsen method for detecting mycobacteria destroys *Paragonimus* eggs.

Antibody Detection. In addition to routine diagnostic methods used to recover the characteristic eggs, immunodiagnostic tests have been used to diagnose pulmonary and extrapulmonary infections and to differentiate tuberculosis from paragonimiasis. CF has been used to diagnose active infections since it was noted that the test became negative soon after the death of the worms. An immunoblot test for the detection of antibodies to *Paragonimus westermani* using adult worm homogenates was found to be highly sensitive and specific; this test has been available at CDC since 1988. Only one false-positive result has been obtained with this method: a patient with *Schistosoma haematobium* infection.

Serology may be useful for the diagnosis of stool- and sputum-negative paragonimiasis, *Paragonimus* cutaneous larval migrans, and cerebral paragonimiasis, although the sensitivity in these conditions is unknown. Also, several species of *Paragonimus* infect humans. The sensitivity of the immunoblot assay for infections caused by these other species is unknown. The sensitivity of this assay is ~96% in proven cases *of P. westermani* in Southeast Asians. The specificity is estimated at 99% with low cross-reaction for *S. haematobium*. Antibodies are often undetectable until 3 weeks postinfection. Although CF titers decline rapidly after treatment, no data for antibody persistence in the immunoblot assay are available.

EIA using adult excretory-secretory antigens was found to be very sensitive for detecting parasite-specific IgG and IgE. Pleural effusion fluid may be more suitable than serum for detection of infections. Dot ELISA has also been used to detect parasite-specific antigen in human sera. Monoclonal antibodies to detect species-specific and stage-specific antigens are highly sensitive and specific for the detection of active infections (87). The serology-based assays are available in areas of endemicity or in specialized diagnostic centers. Most of these assays use nonstandardized reagents and have not been used in clinical trials.

An intradermal test is also available for epidemiologic surveys in areas of endemicity; however, positive reactions persist for years after parasitologic cures have been documented. Purification of antigen for intradermal tests does not improve the efficacy of screening for paragonimiasis, probably due to the nature of skin sensitization evoked by many elements of the parasite but not by a few selected components. The crude worm antigen may be valuable for screening a large population, yet the diagnosis should not depend totally on this test. The final diagnosis should be made by repeated sputum examinations over time, a comprehensive patient history, serologic testing, and radiologic testing if necessary.

Paragonimiasis is rarely described in the United States, which has only one indigenous lung fluke, *Paragonimus kellicotti*. This lung fluke is found in a broad range of mammalian hosts, mainly in the midwestern and southern United States within the Mississippi River Basin. Most cases of autochthonous paragonimiasis in the United States caused by native *P. kellicotti* flukes are transmitted by the ingestion of raw or undercooked crawfish, the preferred crustacean intermediate hosts for *P. kellicotti*. However, as immigration from eastern Asia to the United States and travel between Asia and the United States have increased over the years, more imported cases of *P. westermani* infections have been reported in Asian immigrants and in returning travelers. The *P. kellicotti* antigen Western blot test appears to be more sensitive and specific than the CDC *P. westermani* antigen Western blot test for *P. kellicotti* infections in the United States and may also prove useful in monitoring the effectiveness of therapy with praziquantel. New and more sensitive molecular tests are currently under development and may provide improved diagnosis compared with conventional serological technologies.

Schistosomiasis

Humans become infected with *Schistosoma* spp. by penetration of cercariae through intact skin rather than by the ingestion of metacercariae. Once the cercariae have successfully entered the host, the organism is termed a schistosomulum. After about 48 h, the schistosomulum migrates through the tissues and finally invades a blood vessel. On entry into the blood vessels, the schistosomulum is carried to the lungs and then the liver. Once within the liver sinusoids, the worms begin to mature into adults. Depending on the species, the adult worms are found in various veins. The worms form pairs (male and female), with the female lying in the gynecophoral canal of the male. Development of sexual maturity of female schistosomes depends on the presence of mature male worms.

The eggs are immature when first laid and take approximately 8 to 10 days to develop a mature miracidium. Egg deposition takes place intravascularly. Many of the eggs laid are swept downstream, where they become lodged in the microvasculature of the liver and other organs. About half of the eggs swept away by the bloodstream become embedded in the mesenteric venule wall. The presence of eggs in the tissues stimulates granuloma formation; the eggs die, calcify, and are eventually absorbed by the host.

Disease syndromes associated with schistosomiasis are related to the stage of infection, previous host exposure, worm burden, and host response. Syndromes include cercarial dermatitis, acute schistosomiasis (Katayama syndrome), and related tissue changes resulting from egg deposition.

Specific diagnosis of schistosomiasis by detection of eggs in stool or urine specimens is possible only after egg production has begun. Eggs may be found in feces as early as 5 weeks after infection. The ease of egg detection depends on the worm burden and the duration of the infection. Patients with a low worm burden or old (chronic) infections may have very few eggs in their feces or urine, and the infections may not be confirmed due to the use of insensitive diagnostic methods.

Antibody Detection. A large number of serologic tests have been used in the diagnosis of schistosomiasis; however, most have not been particularly useful because of cross-reactions with other helminth infections, continuation of elevated titers long after the completion of successful treatment, and the slow immunologic response of the host. Because of the complex life cycle, a large number of antigens have been used in serologic tests. Only a few have been useful. The most frequently used tests are the circumoval precipitin test, the cercaria-Hullen reaction, IFA, IHA, immunoblotting, EIA, and FAST-ELISA.

Currently at CDC, specimens are first tested by FAST-ELISA with *S. mansoni* adult microsomal antigen. A positive reaction (>8 U/µl of serum) indicates infection with *Schistosoma* species. The sensitivity is 99% for *S. mansoni* infection, 95% for *S. haematobium* infection, and ≥50% for *S. japonicum* infection. The specificity is 99%. Because of the lower sensitivity for *S. haematobium* and *S. japonicum*, immunoblot analyses relevant to the patient's travel history are performed. As with many other parasitic infections, the presence of antibody indicates infection at some time in the past and cannot be correlated with clinical status, parasite burden, egg production, or prognosis.

EIA methods with soluble adult worm or egg antigens for the detection of antibodies have been used as screening tests, with confirmation of infection performed by EITB tests. Individuals infected with schistosomes have an elevated IgE and IgG4 response, as is commonly seen with other helminthic infections. Few studies have investigated the persistence of antibodies over time after therapy. It is possible that high titers posttherapy reflect treatment failure or reinfection. EIA can be used to screen individuals who have travelled to or resided in areas of endemicity and have had freshwater contact and/or have unexplained eosinophilia. In general, the EIA can be used to investigate eosinophilia, abnormal liver function tests, dysentery, hematuria or fever, and hepatosplenomegaly. Positive reactions detected in a patient with definitive filaria, *T. solium*, *Strongyloides*, or *Echinococcus* infections may represent cross-reactions. Anti-*Schistosoma* antibodies may persist for many months after infection; a single test result must be interpreted with caution when prior infection is possible. Seropositivity may be negative early in Katayama syndrome. The performance of this test in individuals infected with related *S. japonicum* and *S. mekongi* is not currently known.

The dipstick dye immunoassay test (DDIA), developed in China for the detection of antibodies against *S. japonicum*, relies on soluble egg antigen (SEA) labeled with a colloidal dye. This assay is not only rapid, simple, and inexpensive but also particularly useful for screening in the field. Sensitivity and specificity results support the notion that the DDIA with *S. japonicum* SEA can safely be implemented for the diagnosis of *S. mekongi*; however, careful interpretation of results is mandatory when samples are obtained from areas where *Opisthorchis viverrini* is also endemic (88).

Antigen Detection. ELISA methods have also been used to detect circulating schistosome antigens in the sera and urine of infected patients and may be the preferred method of diagnosis. In addition to diagnosis of infection, antigen levels have been used to assess disease severity in terms of intensity of infection and to monitor therapy. Individuals treated with praziquantel experienced a rapid clearance of circulating anodic antigen (CAA) and circulating cathodic antigen (CCA); however, in individuals treated with other therapeutic drugs, clearance may take much longer.

A dipstick assay based on the anti-CCA sandwich ELISA, on a nitrocellulose format, can detect CCA in the urine of patients with *S. mansoni* infection with a sensitivity of 92%. The results were at least as good as those obtained using ELISA or the Kato-Katz fecal smear examination. This rapid, simple approach may lend itself to more extensive use in future screening programs (89). The combination of urine CCA and serum CAA for the detection of circulating antigens and the combination of the *S. haematobium* adult worm microsomal antigen (HAMA) FAST-ELISA and the HAMA EITB for detecting antibodies has significantly improved the sensitivity of antibody and antigen detection (90). However, while CCA dipsticks are a good alternative, or complement, to stool microscopy for field diagnosis of intestinal schistosomiasis, they have no proven value for field diagnosis of urinary schistosomiasis (91).

Another reagent strip assay for the diagnosis of schistosomiasis based on detection of parasite antigens in the urine of infected individuals has been evaluated. The test uses the principle of lateral flow through a nitrocellulose strip of the sample mixed with a colloidal carbon conjugate of a monoclonal antibody specific for *Schistosoma* CCA. The strips and the conjugate in the dry format are stable for at least 3 months at ambient temperature in sealed packages, making the test suitable for transport and use in areas where schistosomiasis is endemic (92).

Using an SEA monoclonal antibody, circulating schistosome antigen was undetectable in serum from patients with other parasitic infections and in 94% of serum samples and 84% of urine samples from *S. mansoni*-infected patients. A significant reduction in circulating schistosome antigen levels was detected in serum and urine samples approximately 12 weeks after praziquantel therapy (93). In another study using a 63-kDa circulating antigen, the antigen was detected in 92% of urine samples from 330 *S. mansoni*-infected individuals, with a 16% false-positive result among 130 noninfected individuals (94).

In reviewing the current status of schistosomiasis diagnosis, the data obtained show that promising new diagnostic tools, especially for *Schistosoma* antigen and DNA detection, which are characterized by high sensitivity and specificity, are being developed. In combination with international funding initiatives, these tools may result in significant steps forward in successful surveillance and disease elimination. Hopefully, more efficient tests will become accessible and self-sustainable for control programs in endemic countries.

Strongyloidiasis

Human infection with *Strongyloides stercoralis* is acquired by skin penetration by filariform larvae (infective larvae) from the soil. These larvae are long and slender and may remain viable in soil or water for several days. After penetration of the skin, they are carried via the cutaneous blood vessels to the lungs, where they break out of the pulmonary capillaries into the alveoli. They then migrate via the respiratory tree to the trachea and pharynx, are swallowed, and enter the mucosa in the duodenum and upper jejunum. Development usually takes about 2 weeks, after which the females begin egg production. The eggs usually hatch, and the rhabditiform larvae (noninfective larvae) pass out of the intestinal tract in the feces. These larvae are passed out onto the soil in the feces and develop into free-living male and female worms, eventually producing infective filariform larvae (eggs, noninfective larvae, and infective larvae). In temperate climates, the free-living male and female worms do not develop; however, the rhabditiform larvae that pass out in the stool develop into the filariform (infective) larvae, which are then ready to infect the next host through skin penetration.

In situations in which autoinfection occurs, some of the rhabditiform larvae within the intestine develop into filariform larvae while passing through the bowel. These larvae can then reinfect the host by (i) invading the intestinal mucosa, traveling via the portal system to the lungs, and returning to the intestine or (ii) being passed out in the feces and penetrating the host on reaching the perianal or perineal skin.

Pathology present in strongyloidiasis can vary, both in severity and in the areas of the body involved. Some individuals remain totally asymptomatic, with the only abnormal clinical finding being a peripheral eosinophilia. Considering the life cycle of the parasite, the three areas of primary involvement would be the skin (cutaneous), the lungs (pulmonary), and the intestinal mucosa (intestinal).

Confirmation of the infection depends on recovery and identification of the adult worms, larvae, or eggs from the stool, duodenal material, or sputum. Fecal specimens may not be positive even after the routine ova and parasite examination, including the concentration procedure, is performed. The numbers of larvae found in the stool also vary from day to day.

Antibody Detection. Although not routinely available, EIA and immunoblot methods have been investigated for use in both the diagnosis and postchemotherapy evaluation of human strongyloidiasis. These methods appeared to be both sensitive and specific, and within about 6 months after therapy they demonstrated a significant decrease in antibody levels. However, in cases where treatment was not effective, the individuals did not show a significant fall in antibody titers. More detailed studies to determine appropriate intervals for serologic evaluation and criteria for successful cure are required before these tests become more widely used.

Currently, EIA, with a sensitivity of 84 to 92%, is recommended. Some patients may be negative, particularly those who are carriers (8 to 16%), and antibody test results cannot be used to differentiate between past and current infection. It is interesting that immunocompromised patients still tend to have detectable IgG antibodies, in spite of their immune system deficiencies.

Strongyloides ratti larval extract was used for the standardization of ELISA to detect genus-specific IgE in humans with strongyloidiasis. A significant positive correlation was found between levels of *Strongyloides*-specific IgE and total IgE in sera from patients with strongyloidiasis. *S. ratti* heterologous extract could be a useful tool for detecting genus-specific IgE by ELISA, thus helping characterize the immune response profile in human strongyloidiasis (95).

A recombinant antigen developed by the National Institutes of Health has been used in an EIA for antibody detection. These tests can be used to screen persons with unexplained eosinophilia, epigastric symptoms, or larva migrans on the trunk. Screening is also appropriate for individuals who have lived or traveled in the tropics or those who will undergo immunosuppressive therapy (transplants, chemotherapy, high-dose corticosteroids). In certain circumstances, positive samples can be tested by immunoblot. This confirmatory assay shows good specificity (98%) with a sensitivity equivalent to the EIA (~95%).

In one study, three immunoassays were evaluated—including the recently released InBios Strongyloides Detect IgG ELISA (InBios International, Inc., Seattle, WA), the SciMedx Strongyloides serology microwell ELISA (SciMedx Corporation, Denville, NJ), and the luciferase immunoprecipitation system (LIPS) assay performed at the National Institutes of Health—for their detection of IgG antibodies to *S. stercoralis*. The overall percent agreement of the InBios, SciMedx, and LIPS assays was comparable at 87.1%, 84.2%, and 89.1%, respectively. However, while the two commercially available ELISAs perform equivalently, neither should be used independently of clinical evaluation to diagnose strongyloidiasis (96).

Antigen Detection. Polyclonal rabbit antiserum was raised against *S. ratti* excretory/secretory (E/S) antigen and utilized to develop an antigen capture ELISA. The assay enabled detection of subpatent rodent *S. ratti* and human *S. stercoralis* infection. No cross-reactivity was observed with purified E/S from *S. japonicum* or the hookworms (*Ancylostoma caninum*, *A. ceylanicum*), nor with fecal samples collected from rodents harboring *Trichuris muris* or *S. mansoni* infection. *Strongyloides* coproantigens that appear stable when frozen as formalin-extracted fecal supernatants stored at –20°C remained positive up to 270 days of storage, whereas supernatants stored at 4°C tested negative. These results indicate that diagnosis of human strongyloidiasis by detection of coproantigen has great potential in the diagnosis of strongyloidiasis (97).

Toxocariasis

Toxocara spp. are non-human-derived ascarids that are capable of undergoing limited development in the human host. Infections with the organism have been classified into two categories: visceral larva migrans (VLM), which is a systemic infection occurring in patients with a mean age of 4.6 ± 3.6 years; and ocular larva migrans (OLM), which also occurs in children. However, concurrent infection with VLM and OLM in the same patient is rare. Eosinophilia, which is pronounced in VLM, is almost absent in OLM. The average age of patients with OLM is also older than that of patients with VLM. The term neural larva migrans is often used when the central nervous system is involved.

Antibody Detection. The clinical diagnosis of toxocariasis can be very difficult, and only fairly recently has a reliable immunodiagnostic test been developed. Serologic test results must be interpreted with care because of the prevalence of asymptomatic infection and the age and socioeconomic status of the individual (98). Previous serologic tests had involved adult- or larval-stage somatic extracts and whole or sectioned larvae. The EIA uses third-stage-larva E/S antigen and is superior to all other serodiagnostic tests. The test is highly specific and does not give cross-reactions with sera obtained from patients infected with other commonly occurring human parasites.

Even though EIA is an extremely sensitive test, the diagnostic predictive value for VLM is significantly different from that for OLM (2) (91). A titer of 1:32 is considered diagnostic for VLM (sensitivity, 78%), whereas a titer of 1:8 is considered diagnostic for OLM (sensitivity, 90%). The specificity is >90% at a titer of ≥1:32. This lower predictive titer for OLM raises the possibility of a false-positive diagnosis in a patient who has an asymptomatic *Toxocara* infection and ocular disease due to other etiology. In addition to serum antibody, vitreous antibody can be measured. Titers in the vitreous fluid were equal to or greater than the serum titers. Measurement of ocular fluid antibody should increase the specificity of the EIA, yielding a better definitive diagnosis for the patient. This test remains the definitive test for the diagnosis of *Toxocara* VLM, despite the lack of good studies of its sensitivity and specificity. The test can be used in the investigation of asymptomatic eosinophilia. The role of this assay in defining the etiology of suspected retinal toxocariasis is not clear.

There is no gold standard test with which the performance of serologic assays for *Toxocara* can be compared; larvae are very rarely identified in the human host. Furthermore, the titers obtained in individuals with clinical VLM vary widely. The sensitivity and specificity estimates (86% and 98%, respectively) apply to infections with *T. canis*. The performance of this test in individuals infected with related species (e.g., *T. leonis*) is not currently known. Cross reactions can occur with other nematode infections (trichinosis, filariasis, strongyloidiasis etc.). The IgG response in toxocariasis is likely to be proportional to the number of infecting larvae.

Trichinosis

Human infection with *Trichinella spiralis* is initiated from the ingestion of raw or poorly cooked pork, bear, walrus, or horse meat or meat from other mammals (carnivores and omnivores) containing viable, infective larvae. The tissue is digested in the stomach and the excysted larvae invade the intestinal mucosa, develop through four larval stages, mature, and mate by the second day. By day 6 of infection, the female worms begin to deposit motile larvae, which are carried by the intestinal lymphatic system or mesenteric venules to the body tissues, primarily striated muscle. Deposition of larvae continues for approximately 4 weeks, with each female producing up to 1,500 larvae in the nonimmune host.

The very active muscles, which have the greatest blood supply—including the diaphragm, muscles of the larynx, tongue, jaws, neck, and ribs, the biceps, and the gastrocnemius—are invaded. The cyst wall results from the host immune response to the presence of the larvae, and the encysted larvae may remain viable for many years, although calcification can occur within less than a year. As few as 5 larvae per g of body muscle can cause death, although 1,000 larvae per g have been recovered from individuals who died from causes other than trichinosis.

Symptoms that may develop within the first 24 h include diarrhea, nausea, abdominal cramps, and general malaise, all of which may suggest food poisoning, particularly if several people are involved. Studies also indicate that the diarrhea can be prolonged, lasting up to 14 weeks (average, 5.8 weeks), with few or no muscle symptoms.

During muscle invasion, there may be fever, facial (particularly periorbital) edema, and muscle pain, swelling, and weakness. The extraocular muscles are usually the first to be involved, followed by the muscles of the jaw and neck, limb flexors, and back. Muscle damage may cause problems in chewing, swallowing, breathing, etc., depending on which muscles are involved. The most severe symptom is myocarditis, which usually develops after the third week; death may occur between the fourth and eighth weeks. Other severe symptoms, which can occur at the same time, may involve the central nervous system. Although *Trichinella* encephalitis is rare, it is life-threatening.

The diagnosis of trichinosis is based on a combination of epidemiology and clinical findings (muscle symptoms, diarrhea, eosinophilia, raised creatine kinase and a high positive or rising *Trichinella* antibody titer). A positive muscle biopsy for *Trichinella* larvae is the gold standard test but is rarely required because the sensitivity of the clinical and laboratory findings listed above is excellent.

Antibody Detection. Serologic tests are very helpful, with the standard two being EIA and bentonite flocculation, which are recommended for trichinosis. EIA detects antigen first and is used for routine screening, and all EIA-positive specimens are tested by bentonite flocculation for confirmation. A positive reaction in both tests indicates infection with *T. spiralis* within the previous few years. Often, antibody levels are not detectable within the first month postinfection. The titers tend to peak in the second or third months postinfection and then decline over a few years. Positive reactions are detected at some point during disease progression in 80 to 100% of all patients with symptomatic disease; detectable antibody usually appears between 3 and 5 weeks after infection.

The EIA sensitivity and specificity estimates (93% and 85%, respectively) apply to infections with *T. spiralis*. The performance of this test with other species (e.g., *Trichinella nativa*) appears to be similar. Cross-reactivity can occur with other helminth infections (e.g., filaria, *Strongyloides*). The IgG response to *T. spiralis* and *T. nativa* infection tends to be slow and is proportional to the number of larvae ingested. Anti-*Trichinella* antibodies can be detected at 2 weeks in most individuals who have consumed a large number of cysts. Less heavily infected individuals may take up to 3 to 4 weeks to mount a detectable IgG response. Antibody titers peak 3 to 6 months after infection and then fall progressively even without treatment. Since low titers may persist for many years after infection, a single test result must be interpreted with caution when prior infection is possible.

Antigen Detection. A modified double-sandwich ELISA has been developed using polyclonal antibodies raised in rabbits and guinea pigs against larval somatic antigens of *T. spiralis*. The first detection of coproantigen was as early as the first day postinfection; the level of coproantigen gradually increased to reach its peak on the seventh day and then decreased to disappear completely during the third week postinfection. Another test, the coagglutination test, was used, and this test confirmed the previous results. Results suggest that the coproantigen detection test could be used to confirm ongoing early *T. spiralis* infection (99).

Intradermal Tests

In the absence of reliable serologic diagnostic tests, skin tests have been used to provide indirect evidence of infection. Most skin tests have been used primarily for research and epidemiologic purposes. Two of the more widely used skin tests are the Casoni and Montenegro tests. In many cases, the antigens used are difficult to obtain and are not commercially available. The antigens are usually crude extracts that have not been standardized and are neither highly sensitive nor specific. They may provoke an immune response that complicates further serologic testing, and there is always the danger of provoking an anaphylactic reaction. In addition, there are ethical questions related to giving patients injections of nonstandardized foreign protein, particularly if the antigens were derived from *in vivo* materials.

Casoni Test

In the past, the Casoni test was the only means of diagnosing exposure to hydatid disease. This intradermal test, in which hydatid cyst fluid is used as the antigen, has many advantages as a result of its simplicity; its nonspecificity has been its major limitation. Diagnostic sensitivity was limited in patients who had intact or hyaline cysts. An immune response was detected more frequently in patients with liver cysts than in those with lung cysts.

False-positive reactions have occurred in patients with other parasitic and nonparasitic diseases. The Casoni antigen may also sensitize the patient, leading to antibody production, and anaphylactic reactions have also been reported. This test is rarely used for diagnostic purposes because of the ethical concerns addressed above.

Casoni's skin test and IHA are still used in Turkey. For 120 patients retrospectively studied during 1997 to 2004, results indicated that an immediate skin reaction to crude hydatid antigens was more useful than IHA (100).

Montenegro Test

The Montenegro test uses formalinized promastigotes of any species of *Leishmania* to evoke a delayed hypersensitivity reaction in infected patients. In some areas, it is the method of choice for diagnosis because of its simplicity.

Patients infected with *Leishmania donovani* (kala azar) have a negative Montenegro test during active disease. The test becomes positive after successful treatment or when there is a spontaneous cure. Problems similar to those mentioned above for the Casoni test have occurred with the Montenegro test. The skin test may induce antibody production and may also cause anaphylactic reactions.

Cestodes
Trematodes
Blood Parasites
Malaria
Leishmania
Trypanosomes
Filarial Nematodes
Appendixes

Often, histology preparations are submitted to the clinical laboratory for review, consultation, or confirmation. Sections of tissue that contain parasites may be seen infrequently in many pathology departments; thus, consultation services are needed (1–6).

This chapter is designed not as a comprehensive presentation of histologic parasitology but rather as a review of parasite morphology, potential sites in the human host, any recommended special processing or stains, and additional helpful hints. The information is arranged in table form according to body site (see Appendix 34.1).

Specific organisms are listed within parasite groups (protozoa, helminths, etc.). Appendix 34.1 does not include organisms that have been reported as only rarely infecting humans. Some of these more rare infections are represented by so few cases that a physician may never see one (see chapter 29). The photographs in Fig. 34.1 to 34.73 illustrate representative parasitic infections in various body tissues. Although most of the specimens are from human tissues, a few are from animals to illustrate a particular parasite and representative body tissue.

Although a great deal of information is contained in this chapter, there has been no attempt to illustrate every organism and every possible tissue involved. Also, identification of parasite adults or immature forms depends on specimen submission and subsequent preparation. If the organisms and tissues are not well preserved, identification may be difficult or impossible. Distinguishing actual organisms from artifact material may also complicate the process.

Most diagnostic procedures in medical parasitology do not require extensive patient information; however, the examination of tissues and final identification of any organisms present can be simplified by reviewing as much information as possible about the patient. Specifics would include current symptoms, recent health status, health status of family members, place of residence, food preferences, travel history, outdoor activities, animal exposure, and any possible unusual environmental exposures. If specific lesions have been identified, the source of the tissue(s) must be identified, as well as the method by which the specimen was obtained. It is particularly relevant to know anything about the status of the specimen regarding adequate fixation and/or any lag time prior to fixation that might influence the overall morphology.

doi:10.1128/9781555819002.ch34

Some general descriptions are provided with diagrams to illustrate specific morphologic criteria used for parasite identification. Because the protozoa are unicellular organisms with one or more nuclei and various organelles, their simplicity does not require extensive descriptive material. However, the identification of various helminths and arthropods requires a more thorough understanding of parasite morphology and appropriate terminology (Appendix 34.2). Appendixes 34.3 to 34.5 contain information on staining characteristics, nuclear and cytoplasmic stains, and specific stains for carbohydrates. This information provides some basic guidelines for the understanding of how various stains are categorized, used, and interpreted. Appendixes 34.6 and 34.7 indicate the locations within the body where human protozoal and helminth parasites are found. Table 34.1 contains very specific information on the musculature of nematodes and can be found following Fig. 34.20 through 34.22. One can also refer to the excellent references provided with this chapter.

Protozoa

Amebae

Entamoeba histolytica

Infection of *E. histolytica* is initiated following ingestion of the cysts of *E. histolytica*; excystation of the cysts in the intestinal lumen produces trophozoites, which colonize the large intestine. The trophozoite may remain confined to the intestinal lumen, feeding on bacteria and cellular debris. Galactose and *N*-acetyl-D-galactosamine (Gal/GalNAc)-specific lectins are used by the trophozoites to aid adherence to colonic mucins. At some point, cysts are formed and subsequently excreted in stool. Colitis results when the trophozoites penetrate the intestinal epithelium. The mechanism involved in superficial epithelium erosion is complex; once the protective mucus barrier has been broken down, trophozoites of *E. histolytica* will adhere and produce damage and lysis of epithelium cell (Fig. 34.1 to 34.5) (7). The first findings seen at sigmoidoscopy include nonspecific thickening of the mucosa or pinhead-size micronodules. The pathological range of amebic colitis extends from mucosal thickening with discrete ulcer formation, separated by regions of normal colonic mucosa, to diffusely inflamed and edematous mucosa. Typical intestinal amebic ulcers are found in the colon (primarily in the cecum), sigmoid colon, and rectum. Nodular and irregular ulcers have been described. Nodular lesions appear as small (0.1- to 0.5-cm), rounded, slightly elevated areas of the mucosa with irregular necrotic centers surrounded by a rim of edematous tissue. The necrotic center may appear depressed or hemorrhagic but more often is filled with a yellowish mucoid material. Irregular or serpiginous ulcers 1 to 5 cm in length are usually found in the cecum and ascending colon. These ulcers are characteristically shallow with broad, elevated margins and are filled with fibrin. Congestion and edema of the narrow strips of uninvolved mucosa and edematous thickening of the entire intestinal wall are frequently observed accompanying these large ulcers. Both types of intestinal ulcers are often present in the same patient.

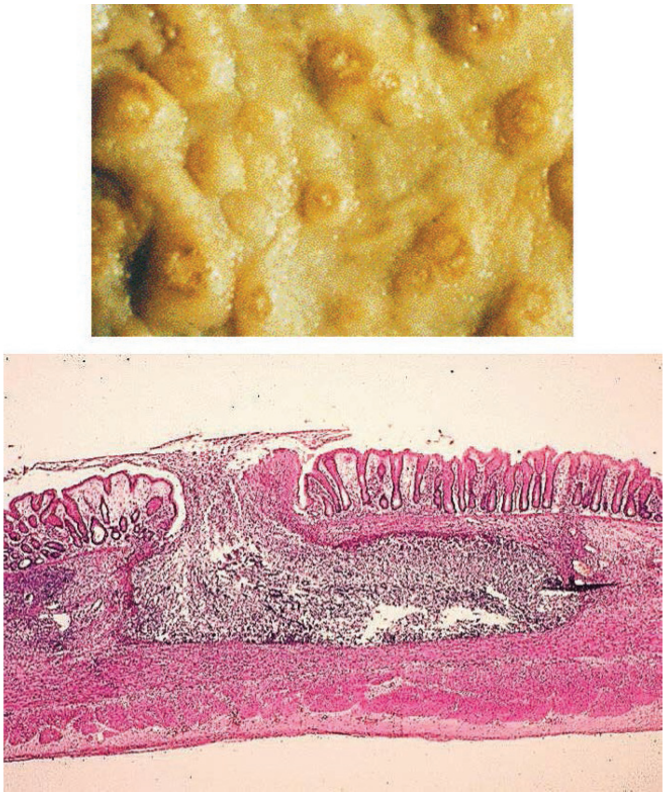

Figure 34.1 Amebic intestinal ulcers. (Upper) Intestinal ulcers; these may coalesce under the surface. (Lower) Note the "flask shape" (small opening on the mucosal surface and a larger area of destruction below the surface); the serosa is edematous and hyperemic. Multiple ulcers may develop and coalesce. Organisms would be found in the healthy tissue border, not in the necrotic material within the ulcer. (Courtesy of the CDC Public Health Image Library, Mae Melvin.)
doi:10.1128/9781555819002.ch34.f1

Mild to moderate neutrophil infiltration is seen within and around capillaries, but small collections can also be identified beneath the surface epithelium. Lymphoid aggregates show reactive hyperplasia with numerous histiocytic cells. Trophozoites are present in small numbers in the surface exudate. As the lesion progresses, there is a mucopenic depression due to loss of mucin from the surface and

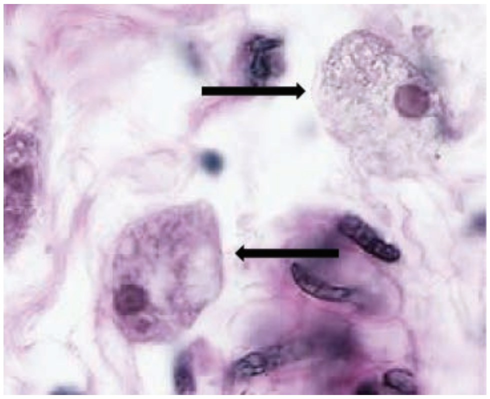

Figure 34.2 Amebic intestinal ulcer. *Entamoeba histolytica* trophozoites in colon tissue (arrows); note the nucleus in each trophozoite (central karyosome); H&E stain (courtesy of the CDC Public Health Image Library).
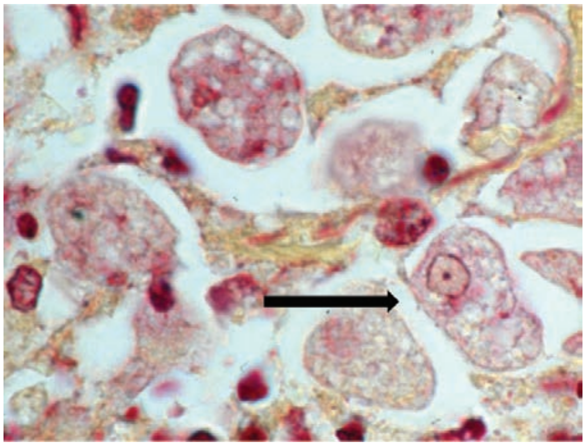
doi:10.1128/9781555819002.ch34.f2

from glandular epithelial cells, which decrease in height from columnar to cuboidal and flattened dividing cells. A larger neutrophil infiltrate is evident, and plasma cells, eosinophils, macrophages, and lymphocytes can also be identified. Organisms may be present in large numbers on the luminal surface but are particularly abundant adjacent to the sites of epithelial lysis. They are surrounded by a proteinaceous exudate composed mainly of fibrin, mucin, erythrocytes, and occasionally neutrophils and mononuclear cells. Invasion of the colonic and cecal mucosa by *E. histolytica* begins in the interglandular epithelium, forming the early invasive lesions with superficial ulceration (Fig. 34.2, 34.3).

Figure 34.3 Amebic intestinal ulcer. *Entamoeba histolytica* trophozoites in colonic ulcer, demonstrating a nucleus with tiny, centrally placed karyosome (arrow). Brown-Hopps stain (Armed Forces Institute of Pathology photograph).
doi:10.1128/9781555819002.ch34.f3



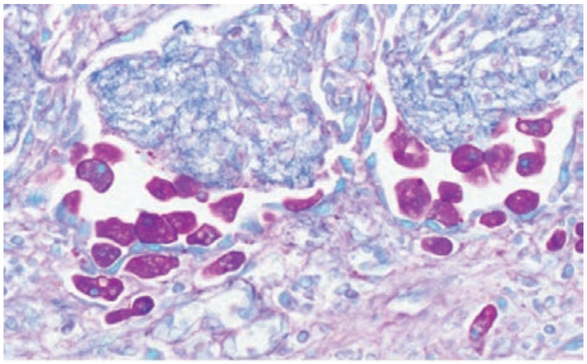


Figure 34.4 Amebic lung section. *Entamoeba histolytica* trophozoites in lung tissue, PAS stain. Note the trophozoites are bright pink and can easily be seen. (Armed Forces Institute of Pathology photograph.) doi:10.1128/9781555819002.ch34.f4

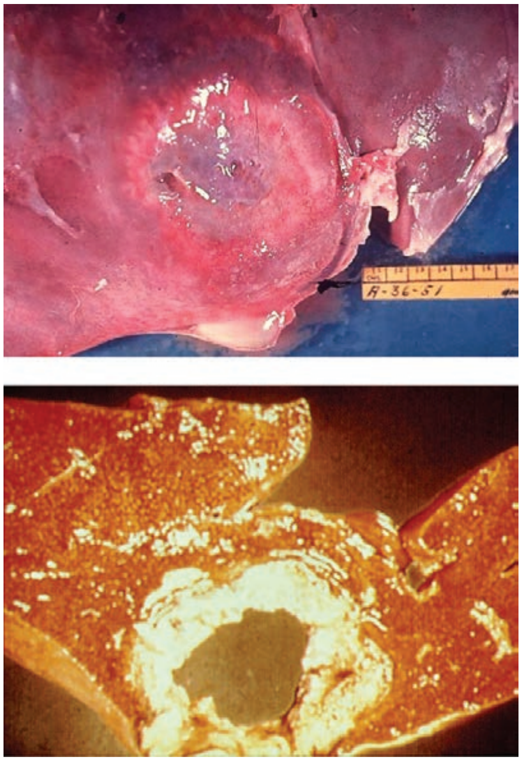
The late invasive lesion is characterized by extension of the mucosal ulcer deep into the submucosa. Once the interglandular epithelium has been invaded by trophozo-

Figure 34.5 Amebic liver abscess. (Upper) Gross image of liver abscess caused by *Entamoeba histolytica*. Note the sunken areas of the abscess. (Lower) Gross image of liver abscess, cut specimen. (Courtesy of the CDC Public Health Image Library, Mae Melvin.)
doi:10.1128/9781555819002.ch34.f5



ites, the underlying tissue offers little resistance, allowing extension of the ulcer laterally, creating the classical flask-shaped amebic ulcer. Histopathology shows necrotic areas and vascular congestion with minimal inflammation in contrast with the extension of the lesion. Trophozoites may be found in the surface layer of the ulcers; bacterial infection causing deficiency of blood supply leads to necrosis, hemorrhage, and gangrene and subsequent perforation of the intestinal wall.

On rare occasions, *E. histolytica* trophozoites enter the bloodstream and disseminate to other body sites (Fig. 34.4 and 34.5). Amebic liver abscess is the most frequent manifestation of extraintestinal amebiasis. Amebic liver abscesses are massive fluid-filled cavities that result from extraintestinal spread of the parasite and can be fatal if untreated.

Histological analysis of liver sections from human amebic liver abscess patients consistently shows massive accumulation of inflammatory cells (primarily neutrophils and macrophages) within the abscess. While these immune cells represent the first line of defense against microorganisms, such an overwhelming immune response and the antimicrobial factors released by inflammatory cells could damage the host tissues as well.

Acanthamoeba spp.

The onset of corneal infection with *Acanthamoeba* spp. can vary tremendously; however, two factors often appear to be involved: trauma and contaminated water. When corneal abrasions occur, the disease process is usually more rapid, with ulceration, corneal infiltration, iritis, scleritis, severe pain, hypopyon (pus in the anterior chamber), and loss of vision. Decreased corneal sensation has contributed to the misdiagnosis of *Acanthamoeba* keratitis as herpes simplex keratitis; this mistake can also be attributed to the presence of irregular epithelial lesions, stromal infiltrative keratitis, and edema, which are commonly seen in herpes simplex keratitis.

Although cutaneous infections are more common in patients with AIDS, regardless of the presence or absence of central nervous system (CNS) involvement, they have also been seen in immunocompetent patients. The disease includes the presence of hard erythematous nodules or skin ulcers. The early lesions appear as firm papulonodules that drain purulent material; these lesions then develop into nonhealing indurated ulcers. Histology reveals necrosis surrounded by inflammatory cells, vasculitis, and the presence of trophozoites and cysts of the amebae (Fig. 34.6).

Granulomatous amebic encephalitis is characterized by confusion, dizziness, drowsiness, nausea, vomiting, headache, lethargy, stiff neck, seizures, and sometimes hemiparesis. Within the CNS, the cerebral hemispheres are the most likely tissue to be involved. There may be edema and hemorrhagic necrosis within the temporal, parietal, and occipital lobes. A chronic inflammatory exudate can be seen over the cortex, mainly of polymorphonuclear leukocytes and mononuclear cells. Unlike in primary amebic meningoencephalitis caused by *Naegleria fowleri*, both trophozoites and cysts are found throughout the tissue. Granulomatous inflammation, necrosis, and thrombosed vessels are seen in the brain. Multinucleated giant cells forming granulomas can be seen in immunocompetent patients, while granuloma formation is generally poor or lacking in immunocompromised individuals.

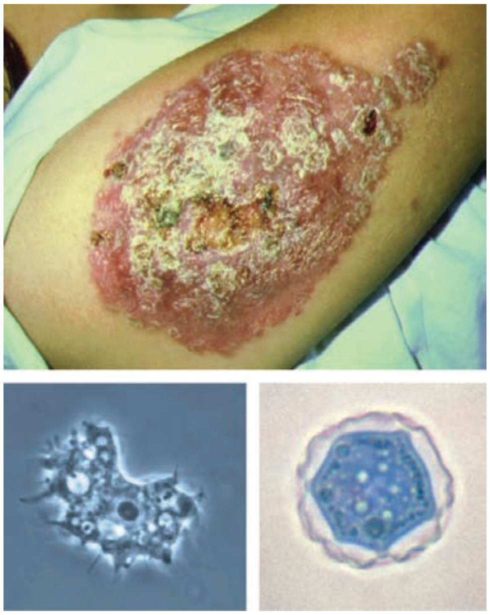


Figure 34.6 *Acanthamoeba* spp. (Upper) Cutaneous abscess on arm; nonhealing ulcer, possibly as a result of a human bite wound, that was not recognized as being caused by *Acanthamoeba* spp. Therapy with routine antibiotics was ineffective. doi:10.1128/9781555819002.ch34.f6

Naegleria fowleri

Primary amebic meningoencephalitis caused by *N. fowleri* is an acute, suppurative infection of the brain and meninges. With extremely rare exceptions, the disease is rapidly fatal in humans. Extensive tissue damage occurs along the path of amebic invasion; the nasopharyngeal mucosa shows ulceration, and the olfactory nerves are inflamed and necrotic. Hemorrhagic necrosis is concentrated in the region of the olfactory bulbs and the base of the brain, with pockets of amebic trophozoites within edematous and hemorrhagic CNS tissue. Organisms can be found in the meninges, perivascular spaces, and sanguinopurulent exudates (Fig. 34.7).

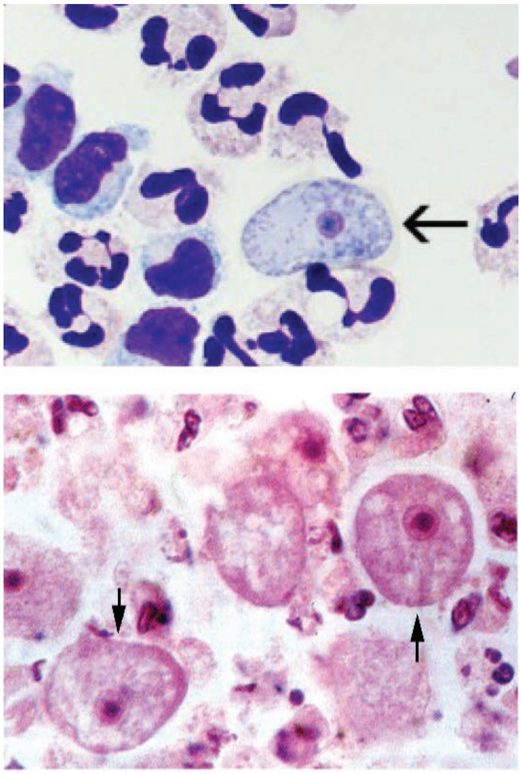

Figure 34.7 *Naegleria fowleri* (primary amebic meningoencephalitis). (Upper) Cytospin of cerebrospinal fluid; note the trophozoite (arrow) with large karyosome (courtesy of the CDC Public Health Image Library). (Lower) *Naegleria* trophozoites in brain tissue; note the large karyosome (from *A Pictorial Presentation of Parasites*: a cooperative collection prepared and/or edited by H. Zaiman). doi:10.1128/9781555819002.ch34.f7

Balamuthia mandrillaris

Over 200 cases of human amebic encephalitis worldwide have been identified, with >30 being seen within the United States. Death can occur from 1 week to several months after the onset of stroke-like symptoms, which can mimic other conditions including brain stem glioma. Patients eventually die of a massive CNS infection (Fig. 34.8). Both trophozoites and cysts of *B. mandrillaris* are found in many of the same CNS tissues as are *Acanthamoeba* spp. Although differentiation of these two organisms in tissue by light microscopy is difficult, *B. mandrillaris* may have more than one nucleolus in the nucleus in some tissue sections. If the route of entry is through broken skin, painless nodules may be observed which develop into lesions containing trophozoites while the patient is alive. Magnetic resonance imaging (MRI) and computed tomography (CT) are useful and will exhibit brain lesions, which are found in the parietal lobe, anterior lobe, temporal lobe, and cerebellum. Lesions have been described as calcified and as forming a mass-like structure. Biopsy may reveal a necrotic cortex and the faint outline of perivascular monocytes.

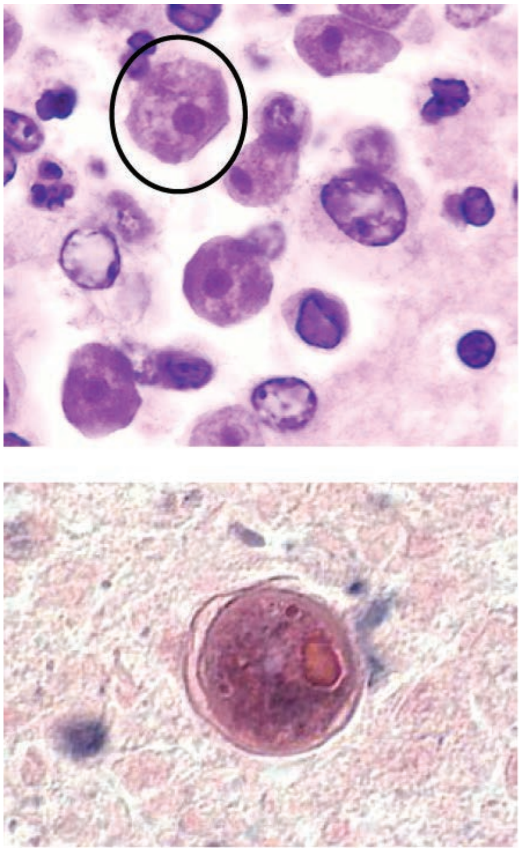

Figure 34.8 *Balamuthia mandrillaris*. (Upper) Trophozoites (circle) are seen in brain tissue. The amebae have the large, characteristic karyosome. The staining of the karyosome is much darker than that of the cytoplasm of the amebae. (Lower) Cyst in brain tissue. (Courtesy of the CDC Public Health Image Library.) doi:10.1128/9781555819002.ch34.f8

Sappinia pedata

The genus *Sappinia* is a newly recognized human pathogen causing amebic encephalitis; there are two species, *S. diploidia* and *S. pedata* (Fig. 34.9). An infection with *S. pedata* has been well documented in a single patient, who survived the infection, while it is not known whether *S. diploidia* can cause human infections. The patient was a 38-year-old man who complained of visual disturbances and headache; he also had a seizure. He had reported a sinus infection prior to the onset of symptoms. Brain scans revealed a solitary tumor-like mass in the posterior left temporal lobe. On biopsy, the mass demonstrated necrotizing hemorrhagic inflammation, which contained free-living amebae. Histologic findings included central necrotic and hemorrhagic inflammations, acute and chronic inflammatory cells without granulomas or eosinophils, and trophozoites present in viable brain parenchyma on mass periphery without inflammatory response.

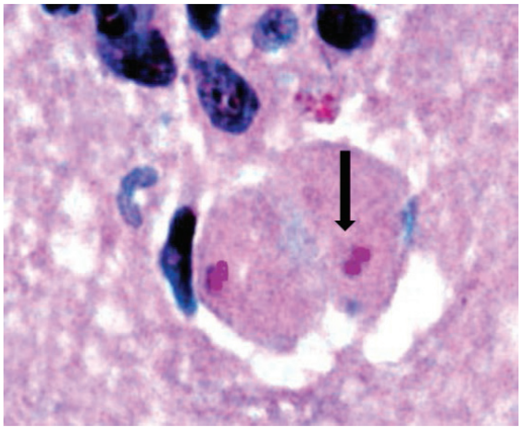

Figure 34.9 *Sappinia pedata*. Trophozoites (arrows) seen in brain tissue; note the presence of two nuclei within some of the trophozoites (arrow) where both are in the same plane of focus (courtesy of the CDC Public Health Image Library). doi:10.1128/9781555819002.ch34.f9

Flagellates

Giardia lamblia

Trophozoites are detectable in the duodenum and proximal jejunum of infected patients (Fig. 34.10). Although there has been some suggestion of mucosal invasion by this parasite, mucosal invasion has generally been found in areas where necrosis or mechanical trauma was present. In reviewing descriptions of general mucosal appearances, there can be a spectrum of change from normal to almost complete villous atrophy, with a greater density of inflammatory infiltrate in the lamina propria when villous atrophy is present. On histologic slides, trophozoites are most commonly found in duodenal mucosa, with other sites less common (jejunal, gastric antral, and ileal mucosas), but rarely in the colon. An entirely normal light-microscopic appearance of the duodenal mucosa can be found in many patients. Mild villous shortening and mild inflammation of the lamina propria were observed in the duodenal mucosa in some patients. Since the histology of the small-bowel mucosa is inconspicuous in the majority of patients with giardiasis, careful review of biopsy specimens must be performed.

Ciliates

Balantidium coli

Symptoms usually include diarrhea or dysentery, tenesmus, nausea, vomiting, anorexia, and headache. Insomnia, muscular weakness, and weight loss have also been reported. The diarrhea may persist for weeks to months prior to the development of dysentery. There may be tremendous fluid loss, with a type of diarrhea similar to that seen in cholera or in some coccidial or microsporidial infections. Following ingestion, excystation releases trophozoites that invade the colonic mucosa, multiply, and form colonies. *B. coli* propagates within the tissue and may produce ulcers and abscesses that extend to the muscular layer. The symptoms of *B. coli*-induced colitis may be confused with amebic colitis. If extensive damage occurs in the wall of the colon, red blood cells (RBCs) may be seen within the trophozoites, as well as in the stool. *B. coli* produces no known toxins; its ability to produce colonic ulcers is attributed to hyaluronidase, which is an enzyme that digests hyaluronic acid, a component of

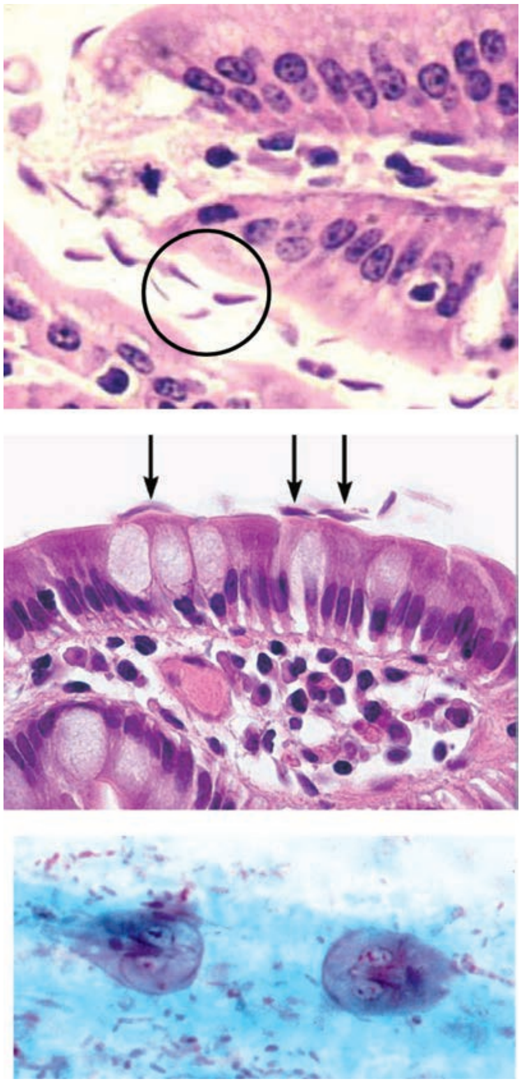

Figure 34.10 *Giardia lamblia* (*duodenalis*, *intestinalis*). (Top) Trophozoites in GI tract (circle). (Middle) Trophozoites on the surface of the duodenal mucosa (arrows) (Armed Forces Institute of Pathology photograph). (Bottom) Trophozoites in mucus from duodenal aspirate, Wheatley's trichrome stain. doi:10.1128/9781555819002.ch34.f10

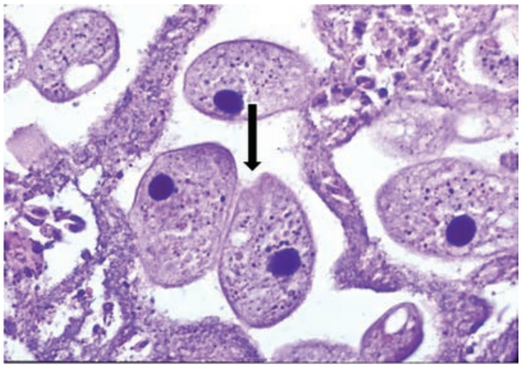

Figure 34.11 *Balantidium coli.* Trophozoites in intestinal tissue; note dark macronucleus and evidence of the oral/feeding groove (arrow). doi:10.1128/9781555819002.ch34.f11

the "glue" holding mucosal epithelial cells together. On contact with the mucosa, *B. coli* may penetrate the mucosa with cellular infiltration in the area of the developing ulcer (Fig. 34.11). Some of the abscess formations may extend to the muscular layer. The ulcers may vary in shape, and the ulcer bed may be full of pus and necrotic debris. Although the number of cases is small, extraintestinal disease has been reported (peritonitis, urinary tract infection, inflammatory vaginitis, pulmonary hemorrhage and respiratory failure, and vertebral osteomyelitis and myelopathy).

Coccidia

Toxoplasma gondii

In immunocompromised patients, the CNS is primarily involved, with diffuse encephalopathy, meningoencephalitis, or cerebral mass lesions. Disseminated toxoplasmosis should be considered in the differential diagnosis of immunocompromised patients with culture-negative sepsis, particularly if combined with neurologic, respiratory, or unexplained skin lesions. It is difficult to demonstrate the parasite in lymph node biopsy specimens, and while some authorities think the histologic appearance is very characteristic, others consider the histologic changes to be nonspecific. However, because many individuals have been exposed to *T. gondii* and may have cysts within the tissues, recovery of organisms from tissue culture or animal inoculation may be misleading, since the organisms may be isolated but may not be the etiologic agent of disease (Fig. 34.12). For this reason, serologic tests are often recommended as the diagnostic approach of choice. However, two representative situations in which the detection of organisms may be very significant are (i) tachyzoite-positive smears and/or tissue cultures inoculated from cerebrospinal fluid and (ii) in patients with acute pulmonary disease, the demonstration of tachyzoites in Giemsa-stained smears of bronchoalveolar lavage fluid, with some tachyzoites being extracellular and some being intracellular.

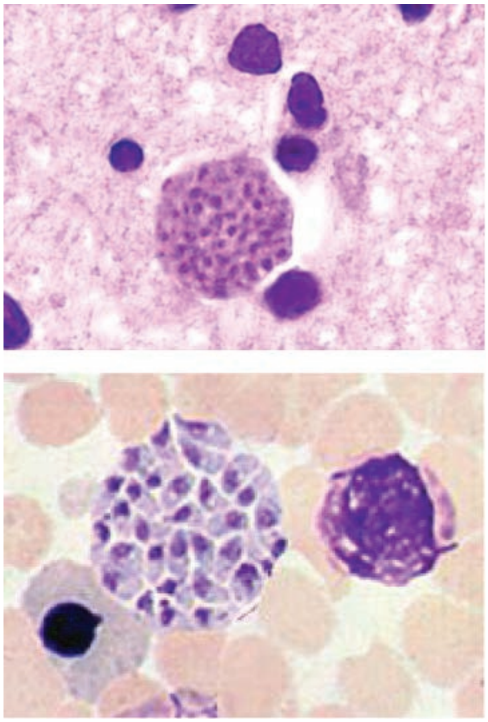

Figure 34.12 *Toxoplasma gondii.* (Upper) Cyst in brain tissue (bradyzoites). (Lower) Tachyzoites in bone marrow. doi:10.1128/9781555819002.ch34.f12

Sarcocystis spp.

Humans can become accidental intermediate hosts for one or more of the 130 known *Sarcocystis* species through ingesting oocysts or sporocysts in food or water contaminated with feces from an infected predator animal. Histopathological differentials include the more common *Toxoplasma* and newer recognized *Neospora* species. Intramuscular infection would be suspected based on symptoms including persistent myalgia, episodic weakness, subcutaneous nodules, dermatomyositis, eosinophilia, and elevated muscle creatinine kinase levels. Often these symptoms, coupled with a history of travel to or living in tropical locations, suggest the next step, which would be a muscle biopsy. Sarcocysts in biopsy specimens can be identified by microscopy of routine histologic sections stained with hematoxylin and eosin (H&E) (Fig. 34.13). Stain variability is common, and periodic acid-Schiff (PAS) positivity of the sarcocyst wall is not always seen. Most sarcocysts in humans have been identified in skeletal and cardiac muscle; however, muscles in the larynx, pharynx, and upper esophagus have also been involved. Sarcocysts are microscopic, up to 700 μm long, and up to 50 μm wide. By light microscopy, the sarcocyst wall is 1 to 2 µm thick. Ultrastructurally, the sarcocyst wall consists of numerous villar protrusions. The villar protrusions are up to 2.8 µm long and 0.4 µm wide, with a tapered end. Microtubules extend from the tip of the villus to the base and occasionally extend deep into the granular layer. The granular layer is approximately 0.5 µm thick. Longitudinally cut bradyzoites were 5.2 by 1.2 (4.8 to 6.5 by 1.0 to 1.3) µm in size (8).

Cryptosporidium spp.

Normal intestinal villi and blunted villi can be seen in Fig. 34.14. Histologically, enteric infections are characterized by villous atrophy, enlarged crypts, and infiltration of the lamina propria by inflammatory cells. Respiratory infections have been characterized by infiltration of the lamina

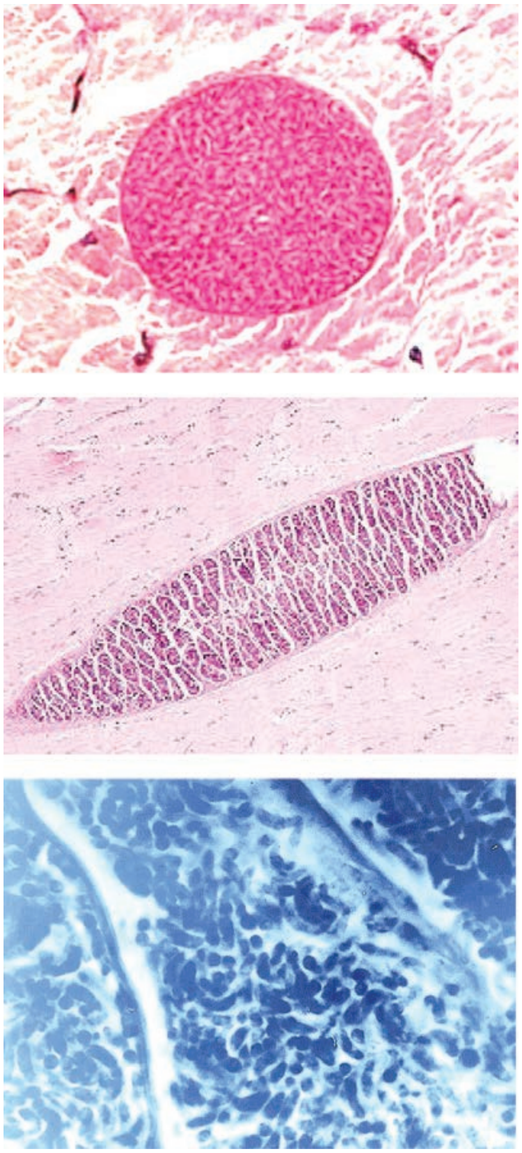

Figure 34.13 *Sarcocystis* spp. (Top) Sarcocyst in tissue. (Middle) Note the septa which are visible in this low-power image. Bradyzoites of *Toxoplasma gondii* in striated muscle resemble *Sarcocystis* spp. However, the *Sarcocystis* bradyzoites are usually more rounded at both ends, and they are contained in larger cysts than those of *Toxoplasma*. (Bottom) The *Sarcocystis* septa are visible, as are the crescentic spores. The sarcocyst wall varies from thin and smooth to thick and striated. Although sarcocysts may be confused with cysts of *Toxoplasma*, sarcocysts tend to be larger and contain larger bradyzoites. (From *A Pictorial Presentation of Parasites*: a cooperative collection prepared and/or edited by H. Zaiman.) doi:10.1128/9781555819002.ch34.f13

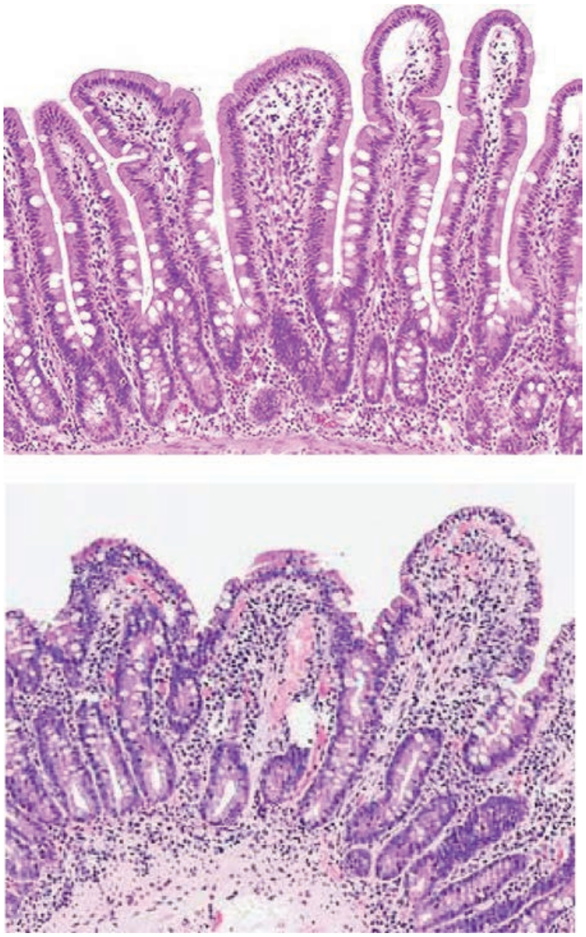
Figure 34.14 Intestinal villi. (Upper) Normal villi are long and slender. (Lower) Blunted villi, typical of histology seen with coccidial infections (*Cryptosporidium* spp., *Cyclospora cayetanensis*) (from reference 14). doi:10.1128/9781555819002.ch34.f14



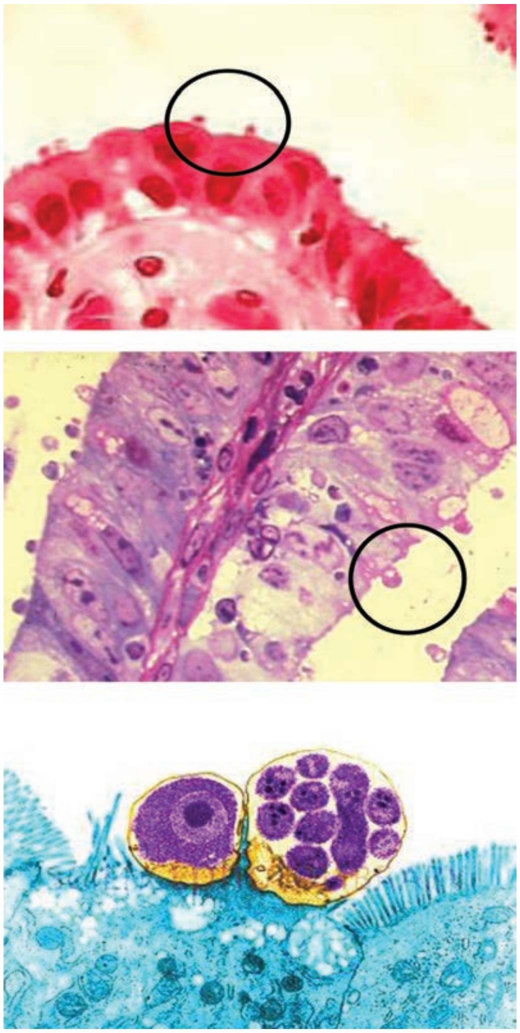


Figure 34.15 *Cryptosporidium* spp. (Top) Organisms shown at the brush border (circle), developing in parasitophorous vacuoles and thus enclosed within membranes of host origin. The mucosal architecture tends to be abnormal, with marked shortening of the villi and hypertrophy of the crypts. (Middle) Organisms shown at the brush border (circle); thick epon section. (Bottom) Color-enhanced transmission electron micrograph showing *Cryptosporidium* (courtesy of the Science Photo Library, http://www.sciencephoto.com/media/445435/view). doi:10.1128/9781555819002.ch34.f15

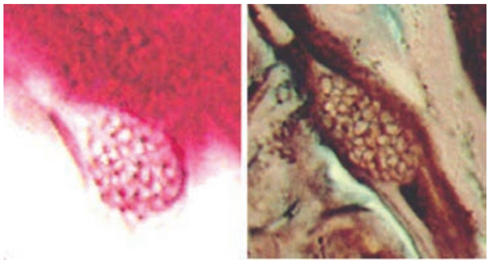
propria by inflammatory cells, loss of cilia, hyperplasia, and hypertrophy of epithelial cells. Similar inflammatory cell infiltration has also been reported for infections involving other organs (Fig. 34.15). Each intracellular stage of *Cryptosporidium* resides within a parasitophorous vacuole within the microvillous region of the host cell. Oocysts undergo sporogony while they are in the host cells and are immediately infective when passed in the stool. Cell damage in enterocyte monolayers has been documented through the disruption of tight cell junctions, a loss of barrier function, the release of lactate dehydrogenase, and increased rates of cell death. Cryptosporidial infection has a predilection for the proximal small bowel, resulting in nonspecific thickening of the duodenum, jejunum, and proximal ileum. Multiple loops of fluid-filled and thickened small bowel loop can be identified on CT.

Microsporidia

It is now well recognized that these unicellular organisms are best described as representing one of many offshoots of the fungal kingdom. Phylogenetic studies have confirmed that the microsporidia evolved from the fungi, being most closely related to the zygomycetes. Other features that are shared with fungi include the presence of chitin and trehalose, similarities in cell cycles, and certain gene organizations. Microsporidia are now considered to be highly derived fungi that underwent genetic and functional losses, thus resulting in one of the smallest eukaryotic genomes known. However, at this point, clinical and diagnostic issues and responsibilities may remain with the parasitologists, and these organisms will be maintained as a part of this parasitology text (Fig. 34.16 to 34.19). Spores are occasionally seen very well by using PAS stain, silver stains, Giemsa stain, or acid-fast stains. Modified Gram stains have also been found to be sensitive although not always standardized. The spore has a small, PAS-positive posterior body, the spore coat stains with silver, and the spores are acid-fast variable. Tissue examination by electron microscopy (EM) is still considered the best approach for identification to the genus/species levels (9–11).

For histologic examination of tissue sections, glutaraldehyde fixation and plastic embedding are highly recommended, even if EM is unavailable. Parasites may be obscured by the host tissue in 6-μm paraffin-embedded preparations.

Figure 34.16 Microsporidia. (Left) Spores in corneal lesion, PAS stain; note the dark-staining dot at the end of each spore. (Right) Spores in corneal lesion, silver stain; note spores appear to be outlined (1,000× oil immersion). Routine histologic testing can be performed by using tissue Gram stains or silver stains. Touch preparations can be methanol fixed and stained with Giemsa stain. Plastic-embedded tissues stained with PAS, silver, acid-fast, and routine H&E stains generally stain better than paraffin-embedded tissues. doi:10.1128/9781555819002.ch34.f16



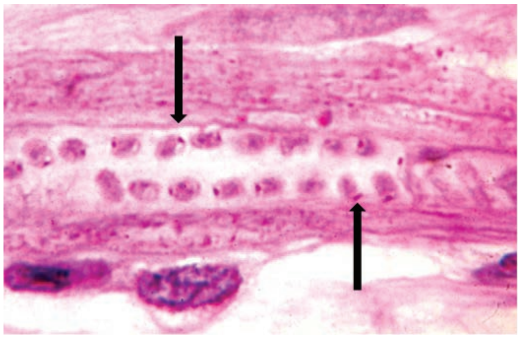


Figure 34.17 Section of appendix showing *Anncaliia connori* spores *in muscularis*. The anterior end of the spore has a PAS-positive granule (arrows) (PAS, ×1,260). (Armed Forces Institute of Pathology photograph.)
doi:10.1128/9781555819002.ch34.f17

Using light microscopy, 1-μm-thick plastic sections, heat-fixed to a glass slide and stained with toluidine blue, provide better visualization of microsporidia because of the thinness of the section. Plastic embedding provides a permanent tissue specimen that can be reevaluated by EM at a later time. Additionally, paraffin-embedded tissue can be deparaffinized and reprocessed for plastic embedding.

***Enterocytozoon bieneusi*.** *Enterocytozoon* was the first genus of microsporidia created for a human infection. Primarily, the organism infects the apical portion of enterocytes of the small bowel and produces a slight flattening of the epithelium (chapter 23, Fig. 23.28). Villus atrophy occurs due to rapid desquamation of infected enterocytes. The parasite can disseminate to the epithelial lining of the common bile duct, gallbladder epithelium, and biliary and respiratory tracts. *E. bieneusi* has been documented most often in male AIDS patients, causing malabsorption resulting in chronic diarrhea, and has been associated with AIDS-related sclerosing cholangitis. This microsporidian has also been documented in HIV-negative individuals with and without diarrhea and has been found in tracheal, bronchial, and nasal epithelium.

***Encephalitozoon* spp.** A case of keratoconjunctivitis and chronic sinusitis due to infection with *Encephalitozoon cuniculi* in an AIDS patient has been reported; diagnosis was confirmed by EM. This species has been found in the liver, as well as peritoneal, cerebral, and disseminated infections in AIDS patients. Several eye infections with *Encephalitozoon hellem* have been found in AIDS patients, including the first reported case of *E. hellem* infecting not only sinuses and conjunctivae but also the nasal epithelium. Overall, this species has been documented in disseminated infections and infection of the sinuses, nasal tissue, tongue, respiratory system, kidneys, and male genital tract.

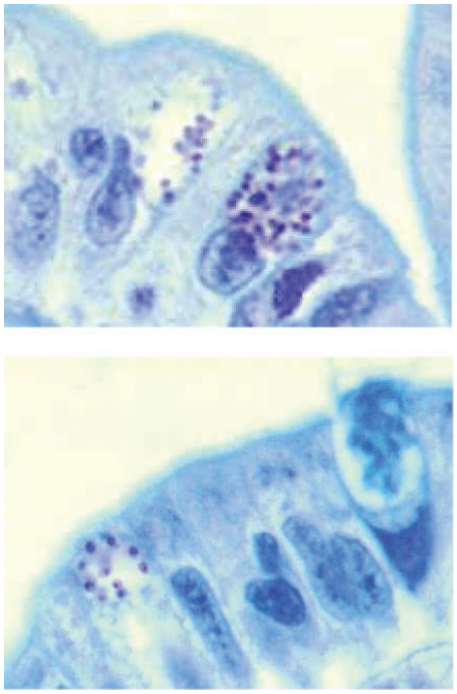

Figure 34.18 Microsporidia in various stages of development in the intestinal enterocytes (1,000× oil immersion). When seen in stool, the spores measure approximately 1 to 3 μm. The microsporidia multiply extensively within the host cell cytoplasm; the life cycle includes repeated divisions by binary fission (merogony) or multiple fission (schizogony) and spore production (sporogony). Both merogony and sporogony can occur in the same cell at the same time. During sporogony, a thick spore wall is formed, providing environmental protection for this infectious stage of the parasite. Microsporidia are characterized by having spores containing a polar tubule, which is an extrusion mechanism for injecting the infective spore contents into host cells. To date, nine genera have been recognized in humans: *Anncaliia*, *Brachiola*, *Encephalitozoon*, *Enterocytozoon*, *Pleistophora*, *Trachipleistophora*, *Vittaforma*, *Microsporidium*, and *Tubulinosema*.
doi:10.1128/9781555819002.ch34.f18

***Encephalitozoon* (*Septata*) *intestinalis*.** *Encephalitozoon (Septata) intestinalis* infects primarily small intestinal enterocytes, but infection does not remain confined to epithelial cells. *E. intestinalis* is also found in lamina propria macrophages, fibroblasts, and endothelial cells. Dissemination to the kidneys, lower airways, and biliary tract appears to occur via infected macrophages. Infections have been reported in the liver, renal system, colon, gallbladder, lungs, sinuses, and conjunctiva.

***Anncaliia* (*Brachiola*, *Nosema*) spp.** *Anncaliia (Brachiola, Nosema) connori* has been identified in human tissues; the spores are oval, measure approximately 2 by 4 μm, and have paired nuclei. The polar tubule has about 11 coils arranged in one to three rows. The single human case

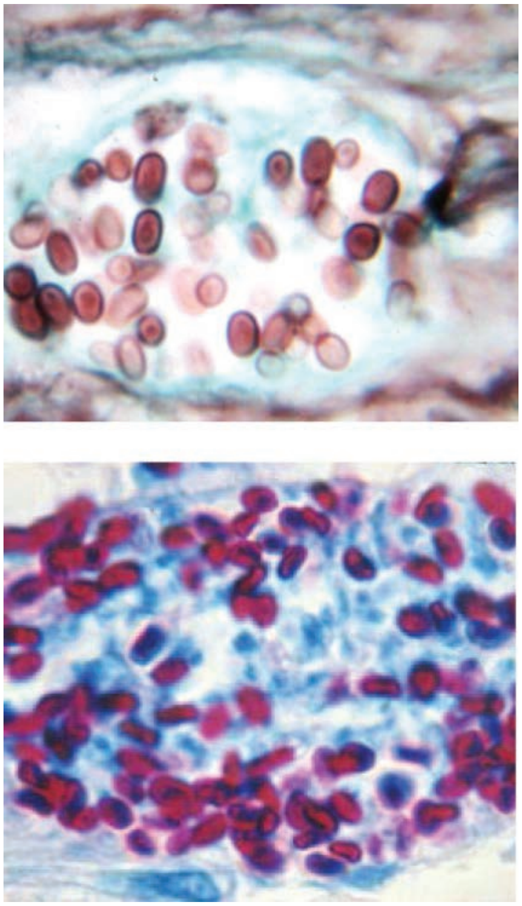

Figure 34.19 (Upper) *Anncaliia connori* spores in wall of ileum; 90-minute Grocott methenamine silver. (Lower) *Anncaliia connori* in myocardium; Ziehl-Neelsen. (Armed Forces Institute of Pathology photographs.) doi:10.1128/9781555819002.ch34.f19

occurred in a 4-month-old infant with combined immunodeficiency disease with a disseminated, fatal infection. Parasites were found in the myocardium, diaphragm, arterial walls, kidney tubules, adrenal cortex, liver, and lungs.

***Anncaliia* (*Brachiola*, *Nosema*) *algerae*.** This microsporidian is apparently transmitted by mosquitoes. Infections have been found in the eye and muscle, possibly from a disseminated case. Both immunocompromised (HIV-negative, but receiving immunosuppressive therapy for rheumatoid arthritis) and immunocompetent patients have become infected. This organism has been known as an insect pathogen for some time. It appears that an initial infection of the eye allows the parasite to adapt to conditions within the mammalian host, thus spreading via macrophages to internal organs.

***Brachiola vesicularum*.** This organism is probably a *Nosema*-like species found in non-HIV-infected patients. Corneal stroma and skeletal muscle were involved in a case in an AIDS patient. Although it was thought that *A. algerae* and *B. vesicularum* might be identical, there are ultrastructural differences between the two organisms. Thus, the designation of two species is currently accepted.

***Microsporidium* spp.** *Microsporidium africanum* was identified in the histiocytes of a corneal ulcer. Although it was first thought to be a *Nosema* sp., electron micrographs confirmed the differences and it was designated *M. africanum*. No information on other hosts is available. *Microsporidium ceylonensis* was found in an eye infection in a child who had been gored by a goat and suffered an eye injury.

***Pleistophora* spp.** Microsporidia of the genus *Pleistophora* have rarely been identified in humans; however, three cases in immunocompetent patients have been reported. In these cases, atrophic and degenerating muscle fibers were full of spores, which were seen in clusters of about 12 organisms, each cluster enclosed by an enveloping membrane, the pansporoblastic membrane. The spores were oval, measuring approximately 2.8 by 3.4 μm. Early biopsies demonstrated atrophic and degenerating muscle fibers; later biopsies showed fibrosis and scarring.

***Trachipleistophora* spp.** *Trachipleistophora hominis* causes severe myositis and sinusitis and was first detected in an AIDS patient. *Trachipleistophora anthropophthera* is the second species in this genus to be described in humans and has been found in brain tissue of two AIDS patients at autopsy; the organisms were also found in the brain, heart, kidney, pancreas, thyroid, parathyroid, liver, bone marrow, lymph nodes, and spleen.

***Vittaforma corneae*.** This organism has been documented in both immunocompromised (urinary tract) and immunocompetent (ocular) patients. An international outbreak of microsporidial keratoconjunctivitis related to soil contact in a Singapore rugby tournament during 2012 has been reported. There were 34/82 (47%) players who were diagnosed with microsporidial keratoconjunctivitis, 3 of which were confirmed as *V. corneae* by PCR (15).

Helminths

Nematodes

See Fig. 34.20 through 34.22 and Table 34.1 for details of the morphology and musculature of the roundworms (Nematodes). There are basically three types of musculature: polymyarian (*Ascaris*), meromyarian (*Enterobius*), and homomyarian (*Trichuris*) (Table 34.1).

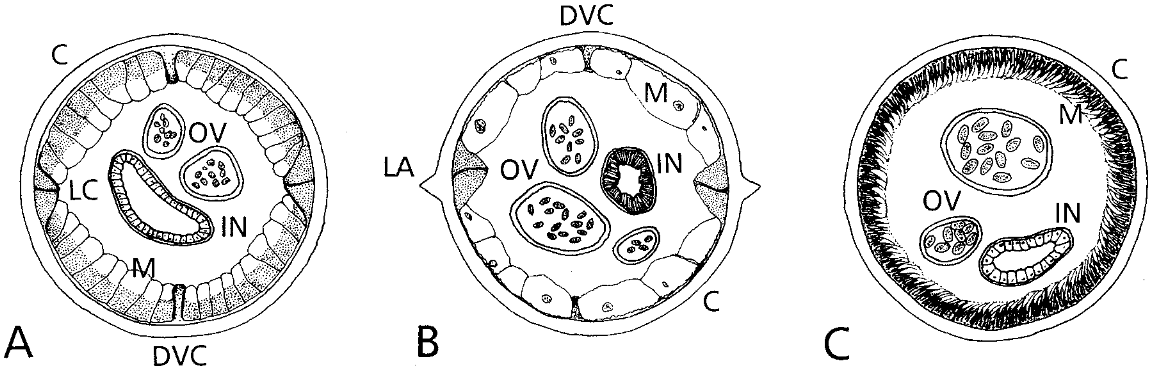

Figure 34.20 Diagram of roundworm musculature morphology in tissue. (A) Polymyarian type. (B) Meromyarian type. (C) Homomyarian type. C, cuticle; DVC, dorsal-ventral chord; IN, intestine; LA, lateral alae; LC, lateral chord; M, muscle; OV, ovary. See Table 34.8. (Illustration by Sharon Belkin.) doi:10.1128/9781555819002.ch34.f20

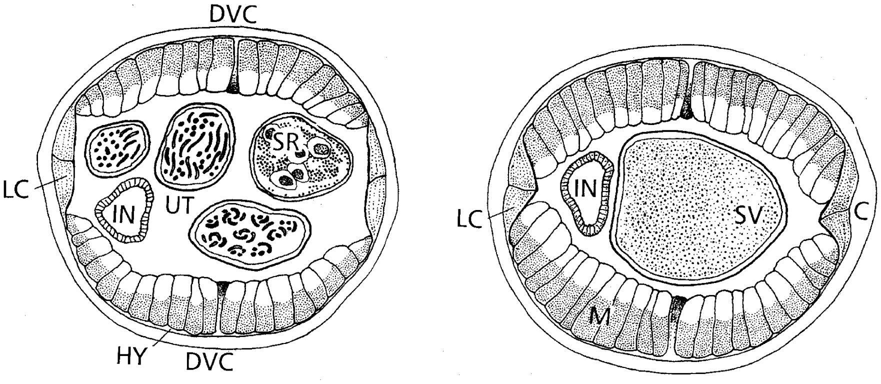
Figure 34.21 Diagram through *Loa loa* (left, female; right, male) (polymyarian type of musculature). Note the well-developed muscle layer divided into four bands separated by the lateral, ventral, and dorsal chords. The muscle cells project into the body cavity. C, cuticle; DVC, dorsal-ventral chord; HY, hypodermis; IN, intestine; LC, lateral chord; M, muscle; SR, seminal receptacle; SV, seminal vesicle; UT, uterus. (Illustration by Sharon Belkin.) doi:10.1128/9781555819002.ch34.f21



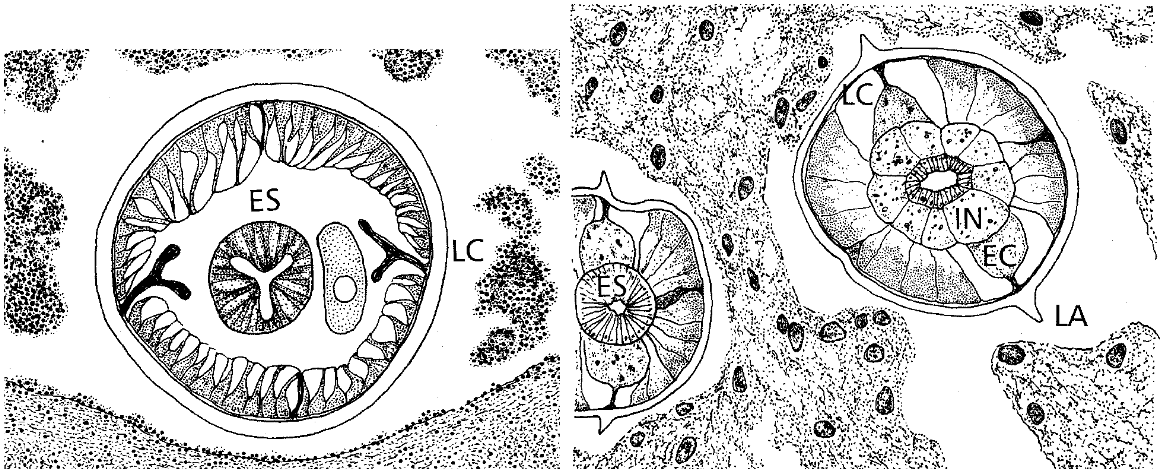


Figure 34.22 Diagram through *Anisakis* (left) and *Baylisascaris procyonis* (right) (polymyarian type of musculature). In *Anisakis*, note the well-developed muscular esophagus (ES) and the Y-shaped lateral chords (LC). In *B. procyonis* (brain tissue), one section is through the esophagus (ES) while the other is through the middle of the body, showing the excretory columns (EC), intestine (IN), and large lateral chords (LC). Note that the lateral alae (LA) are visible in each section. doi:10.1128/9781555819002.ch34.f22

TABLE 34.1 Musculature of nematodes[a]

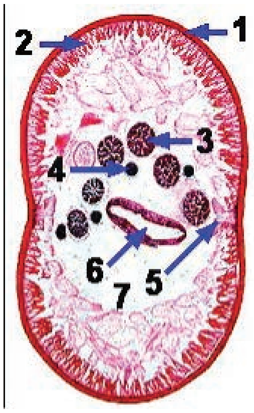
Characteristic	Polymyarian	Meromyarian	Homomyarian
No. of rows of muscle cells	More than 5	Between 2 and 5	Does not exceed 2
Size of cells	Small, uniform	Large, various shapes	Very small, uniform
Arrangement of cells	Projecting into body cavity	Irregular	Regular
No. of cells	Many in each quarter	2 or 3 in each quarter	Many in complete circle
Lateral chords	Present	Present	Absent
Parasites with this type of musculature	*Ascaris*, filaria, *Dracunculus*, *Angiostrongylus*, *Anisakis*	*Enterobius*, hookworms	*Trichuris*, *Trichinella*

[a] Adapted from references 1 to 6.

Ascaris lumbricoides

Although the initial passage of larvae through the liver and lungs usually elicits no symptoms, there can be signs of pneumonitis if the number of larvae is quite large. When the larvae break out of the lung tissue and into the alveoli, there may be some damage to the bronchial epithelium. With reinfection and subsequent larval migrations, there may be intense tissue reactions, even with small numbers of larvae (Fig. 34.23 to 34.25). There may be pronounced tissue reaction around the larvae in the liver and lungs, with infiltration of eosinophils, macrophages, and epithelioid cells. This condition has been called *Ascaris* pneumonitis and is accompanied by an allergic reaction consisting of dyspnea, a dry or productive cough, wheezing or coarse rales, fever (39.9 to 40.0°C), transient eosinophilia, and a chest X ray suggestive of viral pneumonia.

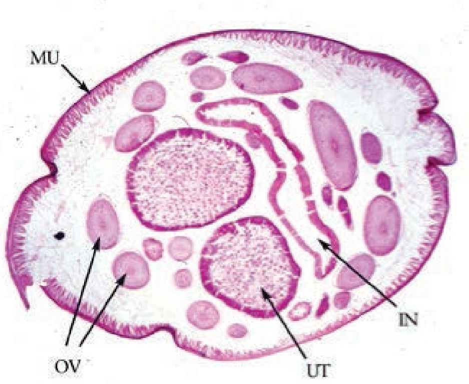
Figure 34.23 Cross section of an adult male *Ascaris lumbricoides*. The section shows the outer protective cuticle secreted by the underlying hypodermis (1). Longitudinal muscle bands (2), dorsal and ventral nerve chords, lateral lines (containing the excretory canals), the intestine, and the pseudocoelom (body cavity) are also visible. The diagram also depicts various sections through the long, coiled testis (4) and vas deferens (3), the latter of which contains the ameboid spermatocytes (sperm cells). Note: These structures may differ in shape, depending on the way they were sectioned. (5) Lateral line with excretory canal; (6) intestine; (7) pseudocoelom. (Courtesy of the Department of Biology, University of Wisconsin-La Crosse, Rick Gillis and Roger J. Haro.) doi:10.1128/9781555819002.ch34.f23



Baylisascaris procyonis

Human infections result from ingestion of eggs that are passed in very large numbers (millions of eggs per day) in the feces of infected raccoons; the human then becomes the accidental intermediate host. Once ingested, the eggs hatch in the intestinal tract, releasing the immature larvae. Rather than developing to adult worms as occurs in the raccoon, the larvae begin to migrate extensively throughout the body tissues, causing visceral larva migrans (VLM) and/or neural larva migrans (NLM). Although this infection presents as acute fulminant eosinophilic meningoencephalitis, two features of the life cycle are somewhat different from those of other helminths causing larva migrans: there is targeted migration to the CNS and continued growth of the larvae to a much larger size within the CNS. Tissue damage is caused by the actual larval migration, as well as an intense inflammatory reaction. Unlike other helminth larvae that cause VLM, the larvae of *B. procyonis*

Figure 34.24 Cross section of an adult female *A. lumbricoides*, stained with H&E. The hypodermis and musculature are visible below the cuticle. Note the presence of the prominent muscle cells (MU), gravid uterus (UT), intestine (IN), and coiled ovary (OV). (Courtesy of the CDC Public Health Image Library.) doi:10.1128/9781555819002.ch34.f24



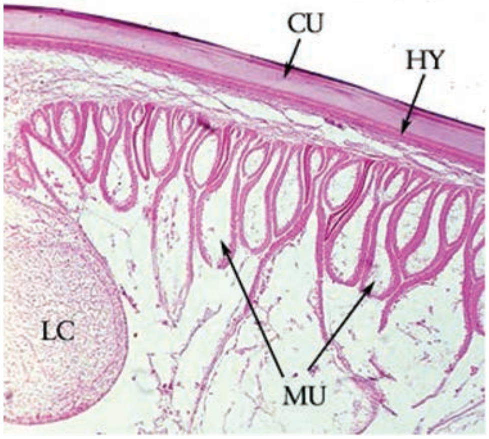


Figure 34.25 Cross section of the cuticle of an adult *A. lumbricoides*, stained with H&E. Shown here are the cuticle (CU) and, immediately below the cuticle, the thin hypodermis (HY). Also shown are the prominent muscle cells (MU) and one of the lateral chords (LC). (Courtesy of the CDC Public Health Image Library.) doi:10.1128/9781555819002.ch34.f25

continue to grow during the migratory phase of the life cycle and can reach lengths of 2 mm. In addition to continued growth, the larvae tend to exhibit very vigorous migratory behavior and remain viable for long periods. They tend to invade the eyes, causing ocular larva migrans (OLM), which has also been found in immunocompetent adults, and the spinal cord and brain, causing NLM, found primarily in infants and young children. Unfortunately, the relatively small brain size in infants or small children increases the potential that larval migration will cause severe clinical disease, including permanent neurologic damage, blindness, or death. Numerous granulomata have been seen in the heart, mediastinal soft tissues, pleura and lungs, small and large bowel walls, and mesentery and mesenteric lymph nodes (4). Nonspecific manifestations of this larval migration include a macular rash primarily on the face and trunk, pneumonitis, and hepatomegaly. The development of dyspnea and tachypnea appears to be secondary to early pulmonary migration. The patients may deteriorate rapidly, progressing to stupor, coma, and death. Survivors are left in a persistent vegetative state or with severe neurologic deficits, including blindness, all of which can require extensive supportive care. Cross sections of larvae tend to measure 60 to 70 μm, and the larvae have prominent, single lateral alae and paired, conical excretory columns (smaller than central intestine) (Fig. 34.26).

Lagochilascaris sp.

Lagochilascariasis is an uncommon parasitic nematode infection found in Latin American countries. It is an intestinal parasite of felines like the cloudy leopard, *Felis nebulosa*. As a zoonosis, lagochilascariasis is transmitted to humans, where it is found subcutaneously in unusual locations like tissues of the neck, eye, lungs, mastoid (hard, bony structure behind the ear), and oropharynx (throat at the back of the mouth). The first sign of infection may be a pustule, usually on the neck, which increases in size to a large swelling. After the skin breaks, living adults, larvae, and eggs are expelled at intervals in the pus. The area of induration increases, with the development of sinus tracts. Chronic granulomatous inflammation may last for months. In addition to humans, it has been found to parasitize humans, domestic cats, dogs, and sylvatic, or forest-dwelling, carnivores (Fig. 34.27).

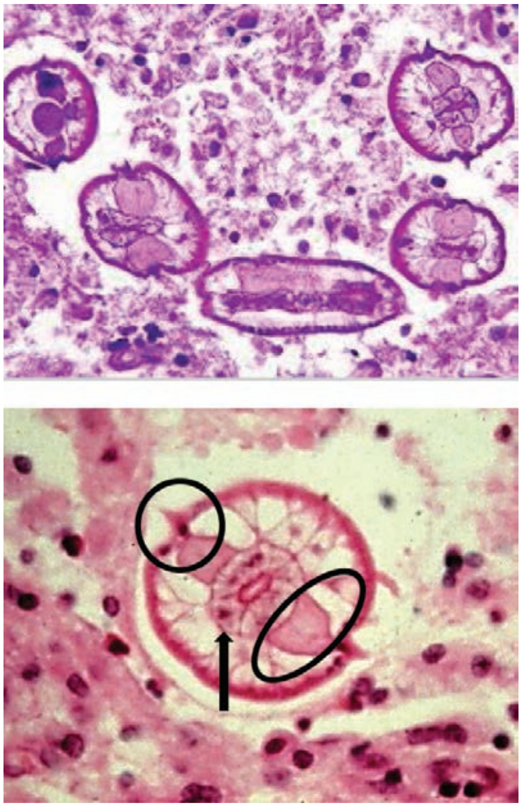

Figure 34.26 *Baylisascaris procyonis*. (Upper) CNS atrophy, sclerosis, and larval granuloma in the brain in a 2-year-old boy who died following 14 months of CNS problems. (Lower) *B. procyonis* larva (polymyarian type of musculature) and inflammation in the corpus callosum of an infected rabbit. Note the prominent alae (circle), excretory columns (oval), and multinuclear intestinal cells (arrow). (See also Fig. 34.22.) doi:10.1128/9781555819002.ch34.f26

Toxocara spp.

VLM Syndrome. The VLM syndrome is most commonly seen in children 1 to 4 years of age; however, rare cases have been seen in adults, in whom the illness includes mild pulmonary involvement suggestive of VLM. The full clinical presentation includes hepatomegaly and pulmo-

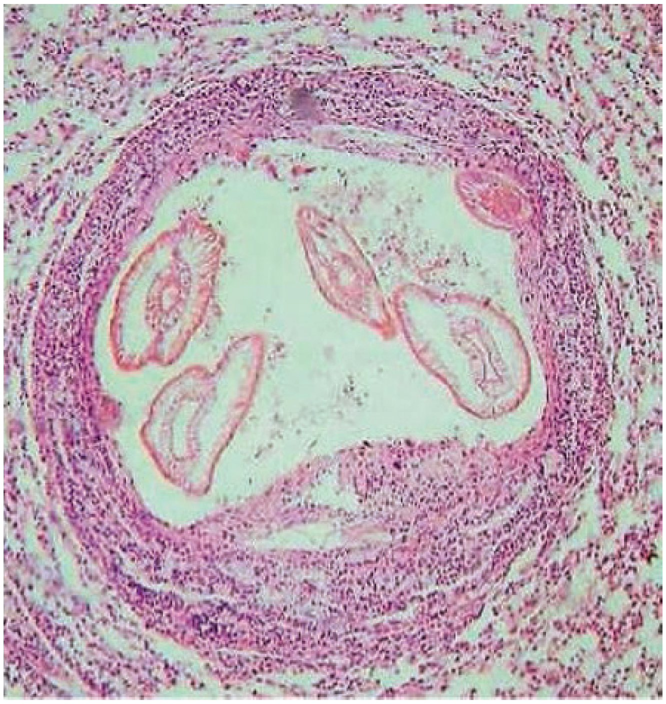

Figure 34.27 *Lagochilascaris* (polymyarian type of musculature) encapsulated larvae in mouse lung tissue with varying degrees of damage, including secondary granuloma containing larvae in different degrees of destruction, concentric fibrosis, and foci of inflammatory infiltration composed of macrophages (H&E). (Courtesy of U.S. National Library of Medicine, National Institutes of Health.) doi:10.1128/9781555819002.ch34.f27

nary infiltrates or nodules accompanied by cough, wheezing, eosinophilia, lymphadenopathy, and fever. Larval entry into the CNS can also result in meningoencephalitis and cerebritis manifesting as seizures. Larvae often remain in the liver and/or lungs, where they become encapsulated in dense fibrous tissue. Other larvae may continue to migrate throughout the body, causing inflammation and granuloma formation.

OLM Syndrome. Evidence suggests that ocular disease can occur in the absence of systemic involvement and vice versa for VLM. Although these facts may be explained by possible strain differences of *Toxocara* spp., VLM may reflect the consequences of the host inflammatory response to waves of migrating larvae while OLM may occur in individuals who have not become sensitized. The resulting inflammation presents clinically as either a granuloma or a granulomatous larval track in the retina or as a condition of the vitreous that resembles endophthalmitis (Fig. 34.28).

Anisakis (Larval Nematodes Acquired from Saltwater Fish)

The majority of the cases of anisakiasis involve gastric anisakiasis. Colonic anisakiasis is extremely rare; fewer than 100 cases have been reported from the United States. However, this infection is probably misdiagnosed and underreported. Human infection is acquired by the ingestion of raw, pickled, salted, or smoked saltwater fish or squid (Fig. 34.29). The larvae often penetrate into the walls of the digestive tract (frequently the stomach), where they become embedded in eosinophilic granulomas. Occasionally, the throat is involved. These large larvae (third stage) measure 1 to 3 cm long or more by 1 mm wide. Histologic sections are characterized by the large body size, moderately thick cuticle, and large lateral cords that extend into the body cavity.

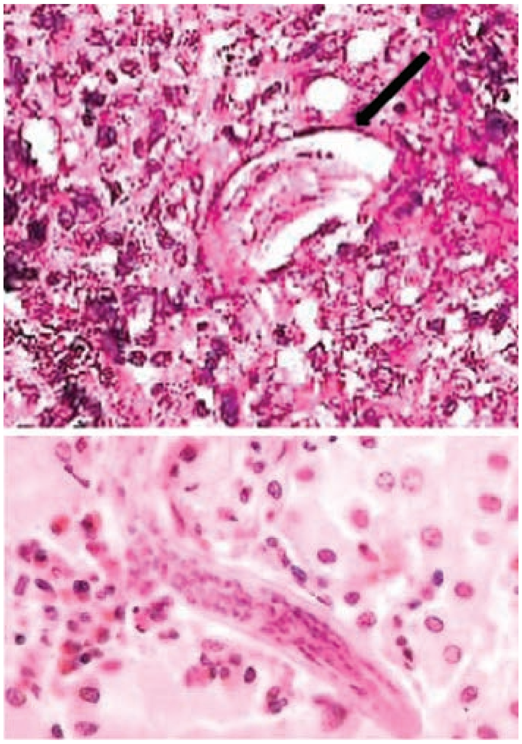

Figure 34.28 *Toxocara*. (Upper) *Toxocara* larva present in the eye (arrow). Eosinophil-rich vitreous abscess contains a fragment of a nematode larva (H&E). (Lower) *Toxocara* larva recovered in liver (visceral larva migrans). (From *A Pictorial Presentation of Parasites*: a cooperative collection prepared and/or edited by H. Zaiman.) doi:10.1128/9781555819002.ch34.f28

Dirofilaria spp.

Human dirofilariasis is typically seen as subcutaneous nodules or as lung parenchyma disease. Patients infected with *Dirofilaria repens* tend to have a subcutaneous lump (face and conjunctiva of the eye and sometimes chest wall, upper arms, thighs, abdominal wall, and male genitalia) (Fig. 34.30). Ocular involvement is usually periorbital, orbital, subconjunctival, or subtenon infection. Human *Dirofilaria immitis* infection is associated with human pulmonary dirofilariasis and is usually asymptomatic. If symptoms are

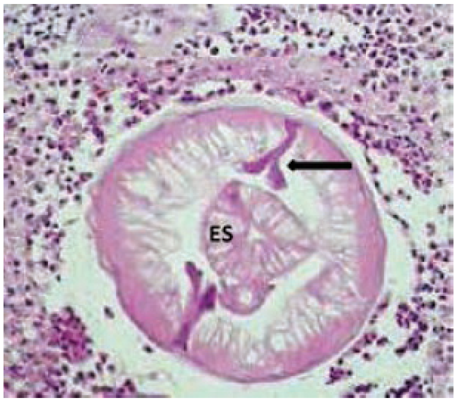

Figure 34.29 *Anisakis* cross section. Note the typical polymyarian type of musculature and the Y-shaped lateral chords (arrow). The large esophagus is in the center of the image (ES). (From *A Pictorial Presentation of Parasites*: a cooperative collection prepared and/or edited by H. Zaiman.) (See also Fig. 34.22.) doi:10.1128/9781555819002.ch34.f29

present, they include cough, chest pain, fever, and pleural effusion. When the worms lodge in the pulmonary artery branches, they cause an infarct. These lesions are usually on the periphery of the lungs and are sharply defined (coin lesion). There is a central necrotic area surrounded by a granulomatous inflammation and a fibrous wall. Dead or dying worms may be found in the lesion. In all cases, histology reveals a histiocyte-rimmed necrotic nodule containing fragments of a partially degenerated *D. immitis* worm, while adjacent lung parenchyma shows morphological features consistent with other pulmonary processes such as extrinsic allergic alveolitis and/or pulmonary vasculitis syndromes. Ocular lesions are usually associated with moderate to severe inflammation. Most cases with eye infections present with pain in the eye, redness, sometimes blurred vision, and swelling of eyelids.

Because the immature larvae may be detected in only a few microscopic sections, careful histologic examination is necessary. The cuticle of nematodes contains chitin, which can be stained with nonspecific whiteners such as calcofluor white. *Dirofilaria* larvae stained with calcofluor white can be easily recognized in tissue sections, whereas the parasite may be difficult to identify using routine histologic stains.

Capillaria hepatica

Capillaria hepatica infection is commonly found in rats, other rodents, and other mammals. Human cases have been reported from various parts of the world, including the United States. Infection occurs via accidental ingestion of eggs from the soil. These eggs hatch and are carried via the portal system to the liver, where the larvae mature in approximately 4 weeks and begin to deposit eggs in the liver parenchyma (Fig. 34.31). Symptoms of this infection

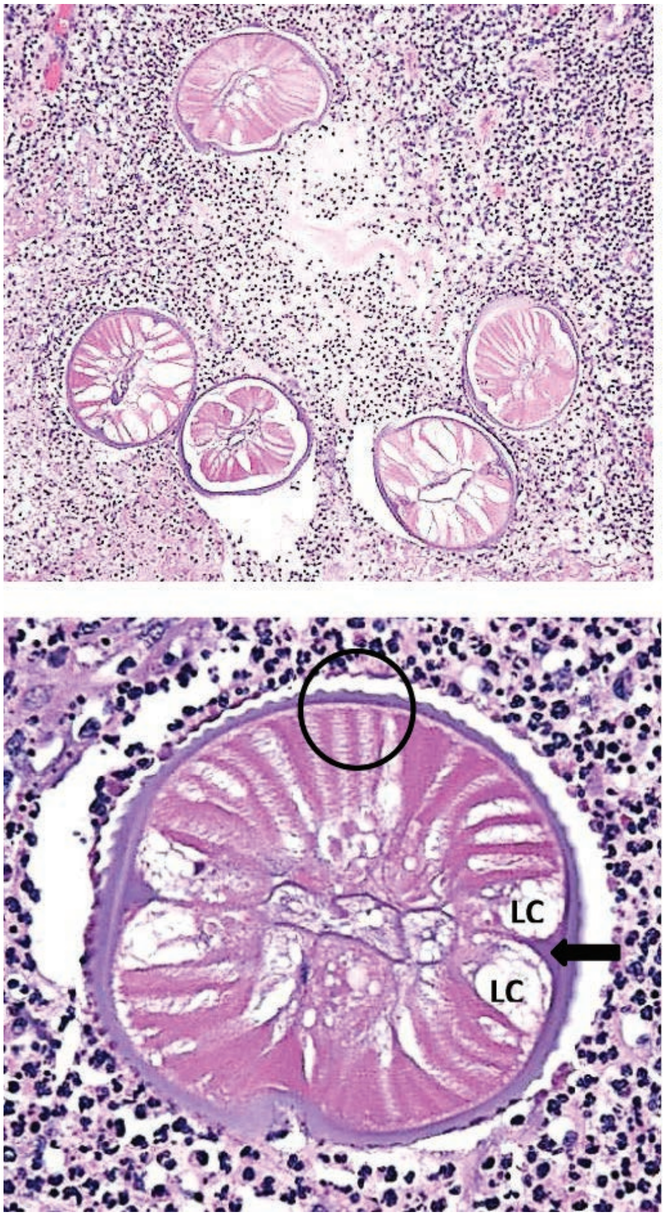

Figure 34.30 *Dirofilaria* sp. (Upper) Note the polymyarian type of musculature and the clearly delineated lateral chords. Also note the longitudinal ridges in the cuticle (bumpy appearance). (Lower) Higher magnification than upper image. Note the typical polymyarian type of musculature and the more clearly delineated longitudinal ridges on the inner surface of the cuticle (circle). The cuticle is relatively thick and multilayered. The very prominent lateral chords are also visible (LC), as is the lateral ridge (arrow); although ventral and dorsal chords are present, they are usually inconspicuous. (Courtesy of Marjorie R. Fowler and Andrea Linscott.) doi:10.1128/9781555819002.ch34.f30

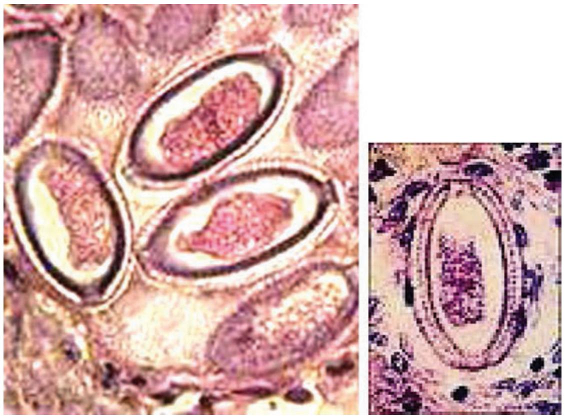

Figure 34.31 *Capillaria hepatica* eggs in liver. These eggs resemble those of *Trichuris trichiura*, but the shells in *Capillaria* eggs are striated. (From *A Pictorial Presentation of Parasites*: a cooperative collection prepared and/or edited by H. Zaiman.)
doi:10.1128/9781555819002.ch34.f31

mimic those of hepatitis, amebic liver abscess, trichinosis, VLM, Loeffler's syndrome, Hodgkin's disease, and histoplasmosis. In a true human infection, no eggs are found in the stool. Diagnosis requires histologic examination. Eggs in liver biopsy specimens can be identified on the basis of their characteristic morphology.

Enterobius vermicularis

Although enterobiasis is an uncommon cause of acute appendicitis in children within the United States, this infection may be associated with acute appendicitis, chronic appendicitis, or ruptured appendicitis, or with no significant symptoms (Fig. 34.32 to 34.34). Other uncommon ectopic sites have included the peritoneal cavity, lungs, liver, urinary tract, and natal cleft. Pathologic examination usually reveals chronic granulomatous inflammation with or without central necrosis, which is surrounded by polymorphonuclear neutrophilic leukocytes, eosinophils, and fibroblasts. Macrophages, giant cells, epithelioid cells, and Charcot-Leyden crystals may also be present. During a case of suspected transverse colon carcinoma, histologic examination of the mass revealed eggs of *E. vermicularis* embedded in granulomatous tissue in the submucosa of the colon; no malignancy was found.

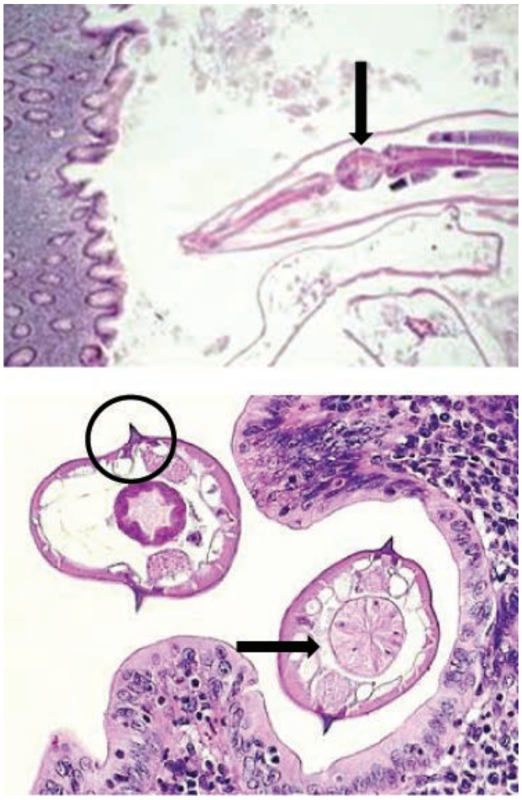

Figure 34.33 (Upper) Longitudinal section of female *Enterobius vermicularis* in the cecum, H&E stain; note the esophageal bulb (arrow) (Korea Society for Parasitology, Sung-Jong Hong). (Lower) Intestinal lumen containing two transverse sections of an *Enterobius vermicularis* worm. This nematode has the meromyarian type of musculature. Note the lateral alae (circle) and intestine (arrow). (Armed Forces Institute of Pathology photograph.)
doi:10.1128/9781555819002.ch34.f33

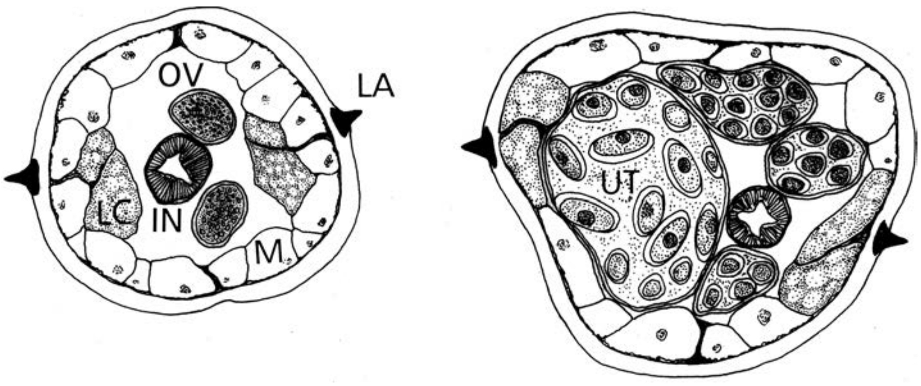

Figure 34.32 Diagram through *Enterobius vermicularis* (both images are of females) (meromyarian type of musculature). Note the very conspicuous lateral alae (LA). The muscle cells (M) are large, of various shapes, and irregular; there are fewer cells per quadrant than seen in the polymyarian type (Fig. 34.20). The lateral chords (LC), intestine (IN), ovary (OV), and uterus (UT) are also visible. (Illustration by Sharon Belkin.)

doi:10.1128/9781555819002.ch34.f34

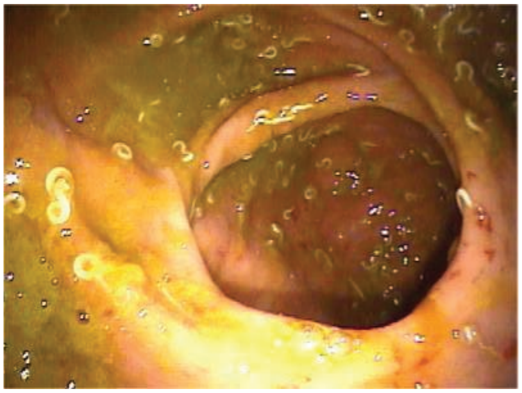

Figure 34.36 Colon heavily infected by *Trichuris trichiura*; photo taken during colonoscopy. (Courtesy of American Association for the Advancement of Science; reference 12.)
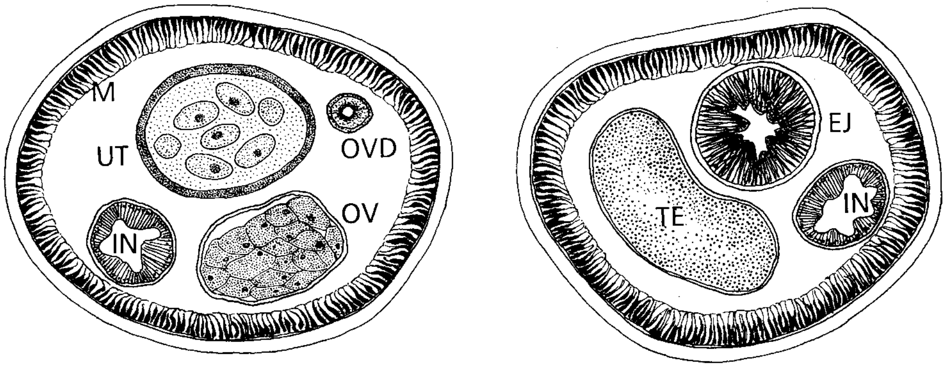
doi:10.1128/9781555819002.ch34.f36

Trichuris trichiura

The adult worms are rarely recovered from the stool, since they are attached to the wall of the intestine. The head portion of the worm is very thin and is embedded in the mucosa, while the posterior end is much thicker and lies free in the lumen of the large intestine (Fig. 34.35 to 34.37). The large, posterior end has been described as the "whip handle" while the thin, anterior end is the "whip" itself, hence the name whipworm. The differential diagnosis of chronic diarrhea requires consideration of several diseases, including celiac disease, inflammatory bowel disease, and irritable bowel syndrome (12). Patients infected with *T. trichiura* may present with a chronic dysentery-like syndrome if they have a massive infestation, leading to anemia and growth retardation. In some cases, diarrhea may last for years without blood and mucus. However, once blood is evident, medical intervention may occur; in some cases the diagnosis requires colonoscopy. Mechanical damage to the mucosa and the allergic response by the host appear to be the main reasons for any abnormalities associated with *T. trichiura* infection and are definitely related to the worm burden, the length of the infection, and the age and overall health status of the host. Although the worm is actually threaded into the epithelium of the cecum, damage produced by this process is minimal unless there is dysen-

Figure 34.35 Diagram through *Trichuris trichiura* (female on the left, male on the right) (homomyarian type of musculature). Note the very small, uniform muscle cells (M) with a regular arrangement, with many cells arranged in a complete circle. Note also the absence of lateral chords. The ejaculatory duct (EJ), intestine (IN), ovary (OV), oviduct (OVD), uterus (UT), and testis (TE) can also be seen. (Illustration by Sharon Belkin.)
doi:10.1128/9781555819002.ch34.f35



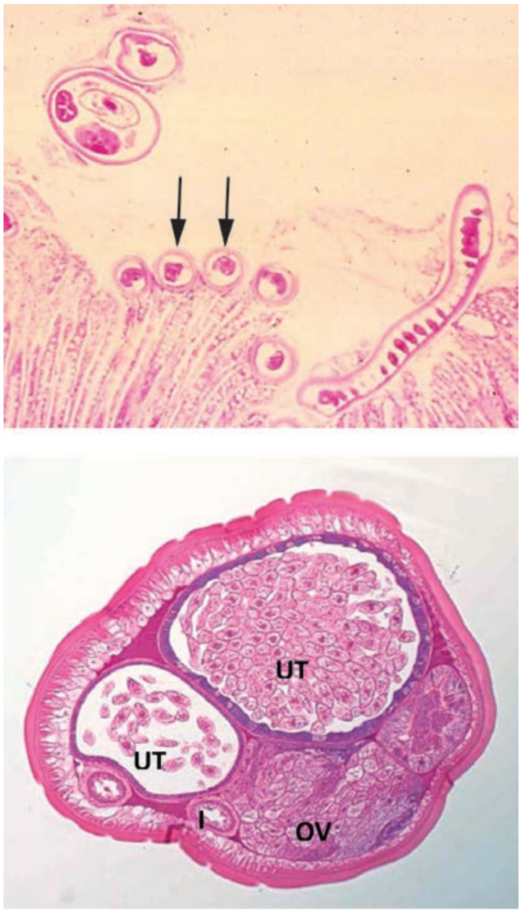


Figure 34.37 *Trichuris trichiura*. (Upper) Several sections of adult male and female *T. trichiura* worms in the colon, showing the narrow anterior portion of the worm within the mucosa ("whip") (arrows) and the thicker posterior portion ("handle") free in the lumen (×15; Armed Forces Institute of Pathology photograph). (Lower) Cross section of female worm (I, intestine; OV, ovary; UT, uterus). The musculature is of the homomyarian type, with very small, uniform, regular cells with many cells in a complete circle. No lateral chords are present. (Courtesy of Andrea Linscott.) doi:10.1128/9781555819002.ch34.f37

tery, during which the mucosa may be edematous and friable, and there may be abdominal cramps, severe rectal tenesmus, and rectal prolapse. The dysentery seen in severe infections may mimic that seen in amebiasis.

Hookworms (*Ancylostoma*, *Necator*)

Adult worms are rarely seen, since they remain firmly attached to the intestinal mucosa by means of well-developed mouth parts (teeth in *Ancylostoma duodenale* and cutting plates in *Necator americanus*) (Fig. 34.38 and 34.39). Symptoms from the intestinal phase of the infection are caused by (i) necrosis of the intestinal tissue within the adult worm mouth and (ii) blood loss by direct ingestion of blood by the worms and continued blood loss from the original attachment site, possibly as a result of anticoagulant secreted by the worm.

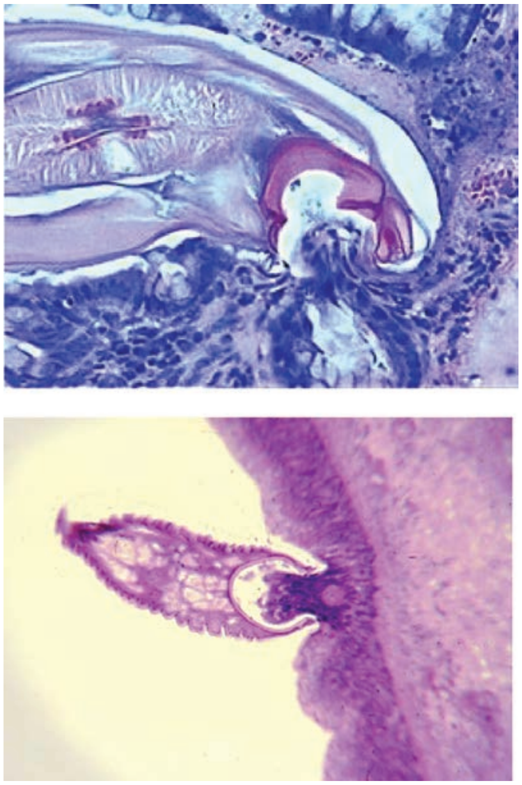

Figure 34.38 *Ancylostoma caninum*. (Upper) Adult hookworm attached to the intestine (courtesy of Richard Bungiro, Yale University). (Lower) Hookworm; section of a worm attached to the mucosa. (From *A Pictorial Presentation of Parasites*: a cooperative collection prepared and/or edited by H. Zaiman.) doi:10.1128/9781555819002.ch34.f38

Trichinella sp.

Human infection is initiated by the ingestion of raw or poorly cooked pork, bear, walrus, or horse meat or meat from other mammals (carnivores and omnivores) containing viable, infective larvae. The very active muscles including the diaphragm, muscles of the larynx, tongue, jaws, neck, and ribs, the biceps, and the gastrocnemius, which have the greatest blood supply, are invaded. The encysted larvae may remain viable for many years, although calcification can occur within less than a year. As few as 5 larvae/g of body muscle can cause death, although 1,000 larvae/g have been recovered from individuals who died from causes other than trichinosis. Pathologic changes due to trichinosis can be classified as (i) intestinal effects and (ii) muscle penetration and larva encapsulation.

During muscle invasion, there may be fever, facial (particularly periorbital) edema, and muscle pain, swelling, and weakness. Other signs are conjunctivitis, headache,

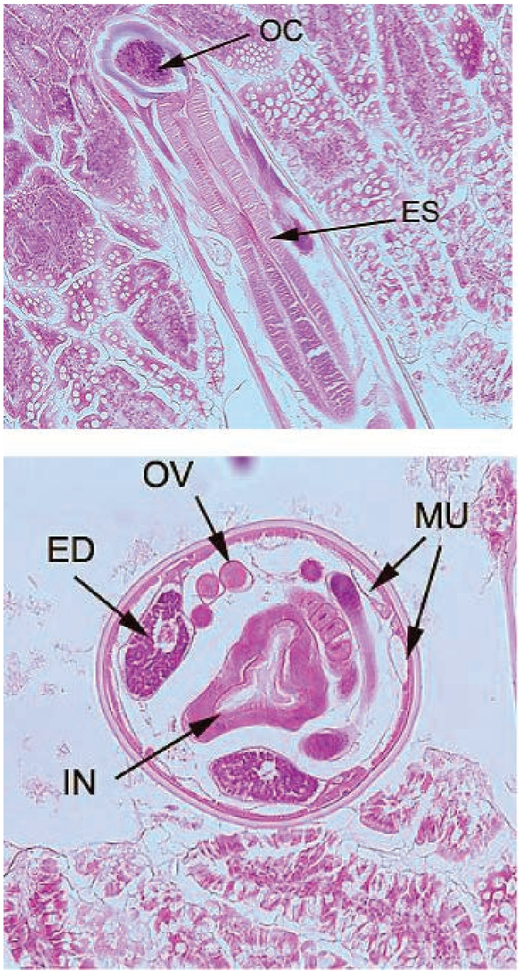

Figure 34.39 Hookworm. (Upper) Longitudinal section of an adult hookworm worm in a bowel biopsy, stained with H&E. Note the oral cavity (OC) and strong, muscled esophagus (ES). (Lower) Cross section of an adult hookworm from the same specimen in upper image. Shown here are the musculature (MU), intestine with brush border (IN), excretory ducts (ED), and coiled ovaries (OV). (Courtesy of the CDC Public Health Image Library.) doi:10.1128/9781555819002.ch34.f39

dry cough, petechial bleedings, and painful movement disorder of the eye muscles. The extraocular muscles are usually the first to be involved, followed by the muscles of the jaw and neck, limb flexors, and back. Muscle damage may cause problems in chewing, swallowing, breathing, etc., depending on which muscles are involved. The most severe symptom is myocarditis, which occurs in approximately 5 to 20% of cases and which usually develops after the third week. Symptoms include pericardial pain, tachycardia, and electrocardiogram abnormalities such as nonspecific ventricular repolarization disturbances, followed by bundle-branch conduction disturbances, and sinus tachycardia. Reversal of the potassium deficit corrects the electrocardiogram abnormalities. Screening should be performed for all patients suspected of having trichinosis; serum troponin provides a simple and reliable means and can be positive even in asymptomatic myocarditis.

It is estimated that 10 to 20% of the patients with trichinosis have CNS involvement and that the mortality rate may reach 50% in these patients if they are not treated. Symptoms may mimic those of polyneuritis, acute anterior poliomyelitis, myasthenia gravis, meningitis, encephalitis, dermatomyositis, and polyarteritis nodosa. There may be focal paresis or paralysis (quadriplegia to single muscle group).

Peripheral eosinophilia of at least 20%, often over 50%, and possibly up to 90% is present during the muscle invasion phase of the infection. Fever can also be present at this time and can persist for several days to weeks, depending on the intensity of the infection. However, once the larvae begin to encapsulate, patient symptoms subside; eventually the cyst wall and larvae calcify (Fig. 34.40).

Muscle biopsy (gastrocnemius, deltoid, and biceps) specimens may be examined by compressing the tissue between two slides and checking the preparation under a microscope at low power (10× objective). However, this

Figure 34.40 *Trichinella spiralis*. (Upper) Encysted larvae in muscle. Although *Trichinella* spp. have the homomyarian type of musculature, the magnification of this image is insufficient to show the details. (Lower) Squash preparation of tissue biopsy specimen. Figure 34.41 Diagram of a transverse section of a *Taenia* proglottid. Under the thick tegument, the underlying parenchyma is divided into cortical (CO) and medullary (ME) layers by a thick band of longitudinal muscles (M). The excretory columns (EC) are clearly visible. Branches of the uterus (UT) and testes (TE) are also seen. (Illustration by Sharon Belkin.) doi:10.1128/9781555819002.ch34.f41

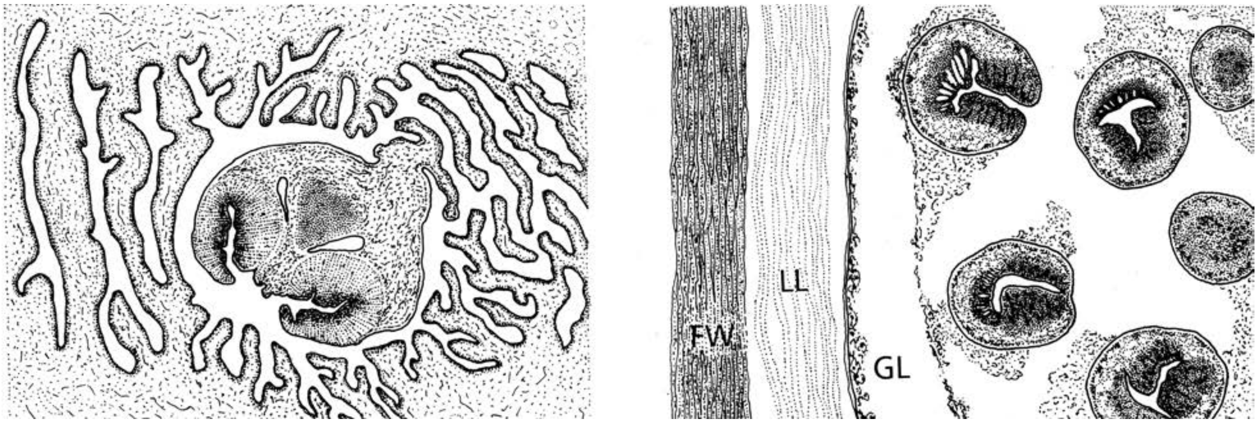
method does not provide positive results until 2 to 3 weeks after the onset of the illness. It is also important to remember that not all species form the capsule.

Cestodes

Taenia solium Cysticercosis, Racemose Cysticercosis

Cysticercosis. Cysticerci have been recovered from all areas of the body, and symptoms depend on the particular body site involved (Fig. 34.41 to 34.45). The presence of cysticerci in the brain represents the most frequent parasitic infection of the human nervous system and the most common cause of adult-onset epilepsy throughout the world. For unknown reasons, in Latin America it is unusual for both brain and muscle cysticercosis to occur in the same patient, with fewer than 6% of patients having cysticerci in both sites. However, elsewhere in the world, subcutaneous involvement by *T. solium* cysticerci has been detected in as many as 78.5% of patients with cerebral cysticercosis (4). Possible reasons for such differences may include (i) the immune status of the patient, (ii) the human leukocyte antigen type, (iii) the nutritional status of the patient, (iv) the burden of eggs infecting the patient, and (v) a difference in the strains of *T. solium*. It is also rare for a patient with cysticercosis to harbor adult *T. solium* worms in the intestine. Neurocysticercosis usually affects males and females of all ages, with a peak incidence between 30 and 50 years of age. It has been estimated that 50,000 individuals die annually due to neurocysticercosis.

Figure 34.42 (Left) Diagram of a cysticercus of *Taenia solium*. The extensively folded spiral canal and a scolex with two large suckers are clearly visible. The denser tissue of the rostellum (between the two suckers) is also visible. In this particular section plane, the hooklets are not visible. Host tissue forms a fibrous capsule around the cysticercus. (Right) Diagram of a unilocular hydatid cyst of *Echinococcus granulosus*. The outer thick fibrous wall is visible (FW) and is produced by the host. Within the fibrous layer is the thinner laminated layer (LL), while right below that layer is the thin germinal epithelial layer (GL) from which daughter cysts and multiple protoscolices arise. Multiple protoscolices within a brood capsule are visible in this illustration. Note that the middle laminated layer is acellular and the thin germinal layer contains some calcareous corpuscles. (Illustration by Sharon Belkin.) doi:10.1128/9781555819002.ch34.f42



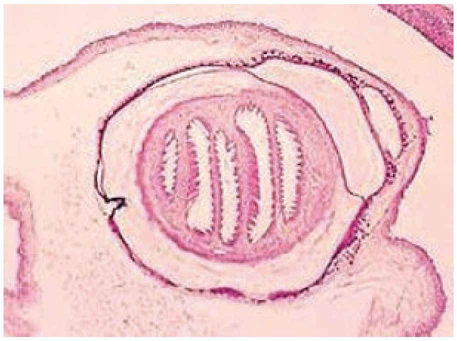


Figure 34.43 *Taenia solium* cysticercus in pig muscle. The cysticercus consists of a fluid-filled bladder containing a single protoscolex. The cysticerci (*T. solium*) have a thick bladder wall, and the rostellum has two rows of hooklets (13 each). Each cysticercus measures 5 to 15 mm long by 4 to 12 mm wide. A convoluted spiral canal leads to the rostellum. The parenchyma usually contains calcareous corpuscles. (From *A Pictorial Presentation of Parasites*: a cooperative collection prepared and/or edited by H. Zaiman. Photograph courtesy of P. M. Schantz.)
doi:10.1128/9781555819002.ch34.f43

Neurocysticercosis is the most common parasitic disease of the CNS; in some countries the prevalence exceeds 10% and is responsible for up to 50% of late-onset epilepsy cases. Although parenchymal cysts are the most common location in the brain, cysts may also be present in the ventricles, meninges, spinal cord, and subarachnoid spaces. Cysticerci have been recovered from the brain (all areas), spinal cord, breast, thyroid, eye (orbit, subretinal), muscles (various sites), mouth, salivary gland, tongue, lip, masseter muscle, pharynx, nose, kidney, lymph nodes, pituitary gland, hypothalamus, parotid gland, submandibular, thorax, scrotum, heart, and subcutaneous tissue, and from disseminated infections.

Cysticerci are milky white, spherical to oval, and usually about 1 cm when developed. Each cyst contains fluid and a single invaginated protoscolex, which has four large spherical suckers and a rostellum armed with a double row of 22 to 36 large and small hooklets. Hooklets are large, readily visible in stained tissue sections, and birefringent and may be acid fast. The wall of the bladder is 100 to 200 µm thick and consists of a tegument, muscle cells, tegumental cells, and parenchyma. The bladder tegument is thin, bears microvilli on the outer surface, and is frequently raised into projections 10 to 25 µm wide. Smooth muscle fibers lie beneath the tegument and extend into the parenchyma, with a row of tegumental cells lying below the muscle fibers. The parenchyma consists of loose stroma, fluid-filled spaces, calcareous bodies, mesenchymal fibers, and smooth muscle.

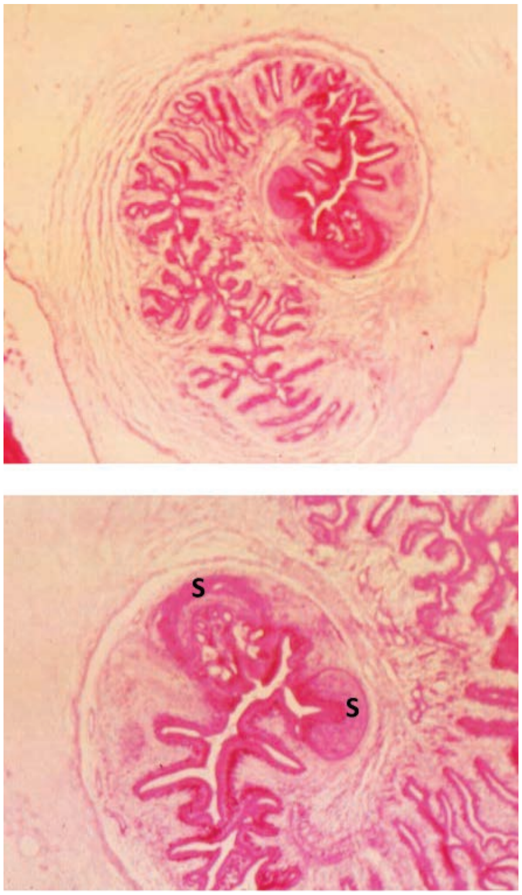

Figure 34.44 *Taenia solium.* (Upper) Subcutaneous nodule from a patient. (Lower) Higher magnification than upper figure; note the suckers (S). (From *A Pictorial Presentation of Parasites*: a cooperative collection prepared and/or edited by H. Zaiman. Photograph courtesy of K. Juniper, Jr.)
doi:10.1128/9781555819002.ch34.f44

Racemose Cysticercosis. The racemose form consists of several various-sized bladders forming an irregular mass (resembling a grape cluster), usually without a protoscolex (Fig. 34.46). The origin of the racemose cysticercus is unknown. Some believe it may be an aberrant *T. solium* cysticercus, or be formed as the scolex disintegrates, but the bladder wall continues to grow and proliferate (similar to a metastatic cancer). Neurocysticercosis coinfection is likely to be increasingly recognized in patients with HIV and should be included in the differential diagnosis of CNS infections in these patients.

Hymenolepis (*Rodentolepis*) *nana*

Infection is usually acquired by the ingestion of infective *Hymenolepis nana* eggs, primarily from human stool (direct life cycle). The eggs hatch in the stomach or small intestine, and the liberated larvae, or oncospheres, penetrate the villi in the upper small intestine. The larvae develop into the cysticercoid stage in the tissue and migrate back into the lumen of the small intestine, where they

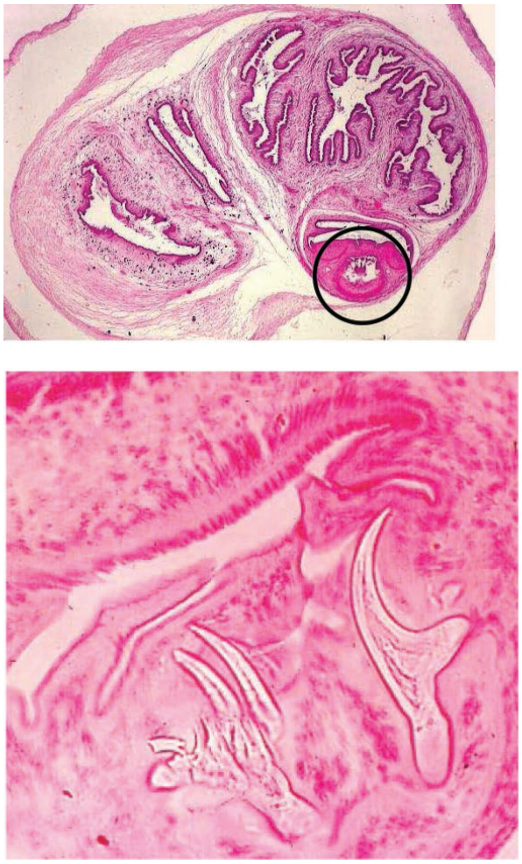

Figure 34.45 Cysticercus. (Upper) Scolex of a cysticercus showing a sucker and hooklets of *Taenia solium* (circle); note the hooklets are barely visible. (Lower) Enlarged image of the hooklets within the cysticercus. (Armed Forces Institute of Pathology photographs.) doi:10.1128/9781555819002.ch34.f45

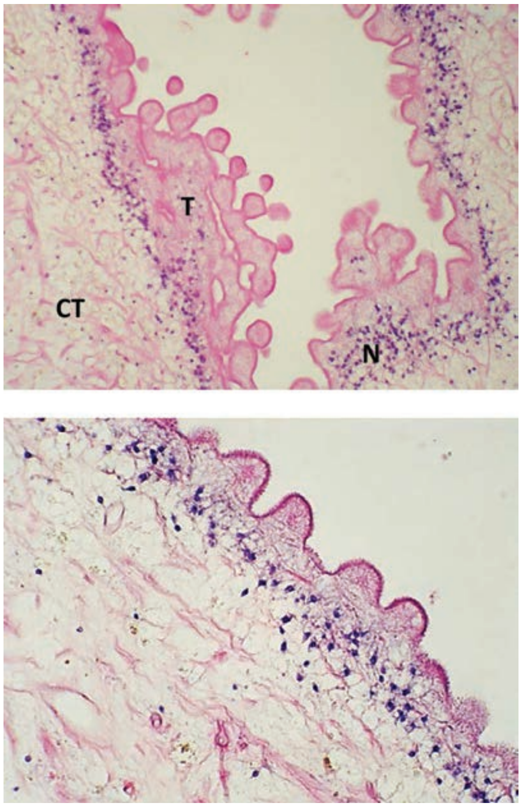

Figure 34.46 *Taenia solium* racemose cyst in the brain. (Upper) The bladder wall of the racemose cysticercus has three separate layers. The tegumental surface has wart-like protuberances and is acidophilic (T). Beneath the tegument are small, rounded, pyknotic nuclei (N). The innermost layer is made up of loose connective tissue (CT). (Lower) Higher magnification. (From *A Pictorial Presentation of Parasites*: a cooperative collection prepared and/or edited by H. Zaiman.)
doi:10.1128/9781555819002.ch34.f46

attach to the mucosa (Fig. 34.47). The adult worms mature within several weeks. They are very small compared with worms of the *Taenia* species and measure up to 40 mm long. The fact that an intermediate host is not required in the life cycle was determined in the late 1800s. For this reason, *H. nana* has been considered to be the most common tapeworm throughout the world, and it is estimated that 50 million to 75 million people worldwide are infected. The infection is most commonly seen in children, although adults are also infected.

Echinococcus granulosus Hydatid Disease (Cystic Disease)

The most common site for hydatid disease in humans is the liver (60 to 70% of cases) (Fig. 34.48 and 34.49). Although not all oncospheres survive passage through the body, those that do survive begin to grow and develop. Usually by the fifth month, the wall of the hydatid cyst has become differentiated into an outer friable, laminated, nonnucleated layer and an inner nucleated germinal layer. Various daughter cysts (brood capsules) bud off from the inner germinal layer and may remain attached or float free in the interior of the fluid-filled cyst. The individual protoscolices bud off from the inner wall of the daughter cysts; these protoscolices and free daughter cysts are called hydatid sand. Each scolex normally invaginates to protect the hooklets. Although not every cyst produces daughter cysts and/or protoscolices, this general tissue organization is called a unilocular cyst, in which the cyst contents are held within a single limiting cyst wall.

The metacestode of *Echinococcus granulosus* is a white, spherical, fluid-filled cyst that can vary from a few millimeters to many centimeters in size, containing brood capsules with protoscolices. The cyst wall has multiple layers. The thin inner layer (germinal membrane) possesses

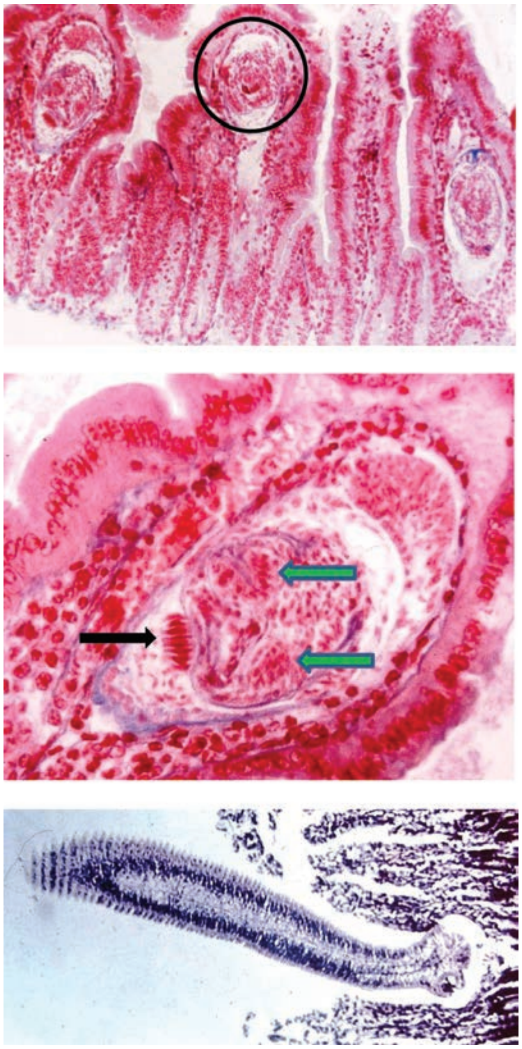

Figure 34.47 *Hymenolepis nana* cysticerci in the villi of a mouse. (Top) When mature, these cysticerci (circle) emerge, attach to the intestinal wall, and develop into the adult worm (same life cycle seen in humans). (Middle) Note the curved suckers (green arrows) and hooklets (black arrow). (Bottom) Section through *H. nana* embedded in the mucosa. (From *A Pictorial Presentation of Parasites*: a cooperative collection prepared and/or edited by H. Zaiman. Photograph courtesy of B. Gueft; specimen courtesy of M. Yoeli.) doi:10.1128/9781555819002.ch34.f47

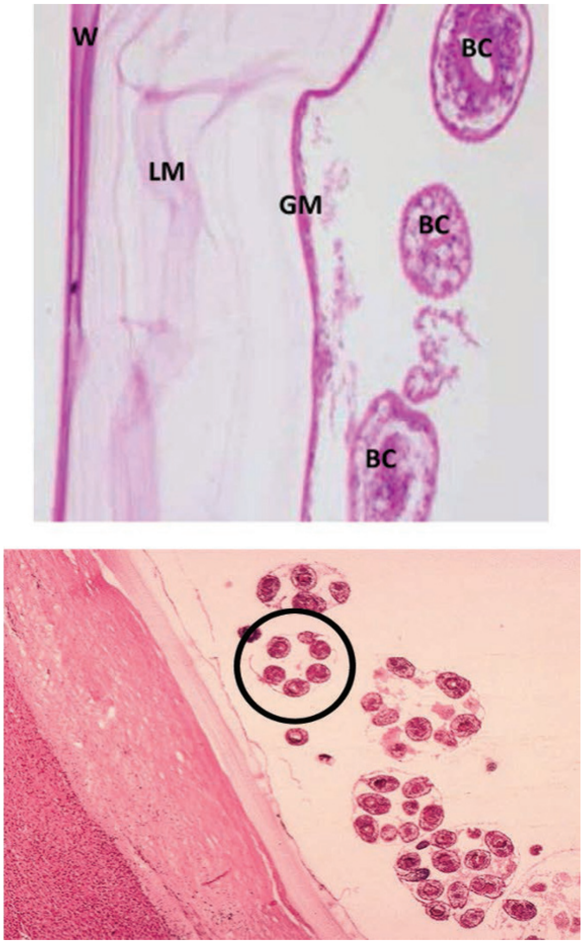

Figure 34.48 (Upper) *Echinococcus granulosus* brood capsules (BC) arising from the germinal membrane (GM). The fibrinous wall of the host (W) and the laminated membrane (LM) are also seen. (Armed Forces Institute of Pathology photograph.) (Lower) Hydatid cyst; note the layers and brood capsules filled with protoscolices (circle) (courtesy of CDC Public Health Image Library, Peter Schantz). doi:10.1128/9781555819002.ch34.f48

nuclei and occasionally calcareous corpuscles. The outer layer (laminated membrane) is approximately 1 mm thick. Although the layering can be seen with H&E stain, it is more distinct using Gomori methenamine-silver stain (GMS). The protoscolices are ovoid and measure approximately 100 μm; each one contains four suckers, many calcareous corpuscles, and two rows of hooklets, one large and one small. The hooklets can be stained (GMS, acid-fast, Ryan blue modified trichrome), but appear birefringent. Most are invaginated; however, some may be evaginated. Some cysts in humans are sterile and do not produce brood capsules, daughter cysts, or protoscolices.

Severe symptoms can occur if the cyst ruptures spontaneously, from trauma, or during surgery. In addition to the spread of tissue from which additional hydatid cysts can grow, there may be serious allergic reactions, including rash, anaphylactic shock, or death. Cyst rupture can also lead to cholangitis and cholestasis. Morbidity and mortality rates associated with perforated hydatid cysts are higher than those associated with nonperforated cysts. Lung, brain, spinal, and orbital hydatid cysts have been more commonly seen in younger patients. It is thought that age somehow alters the host-parasite relationship and thus af-

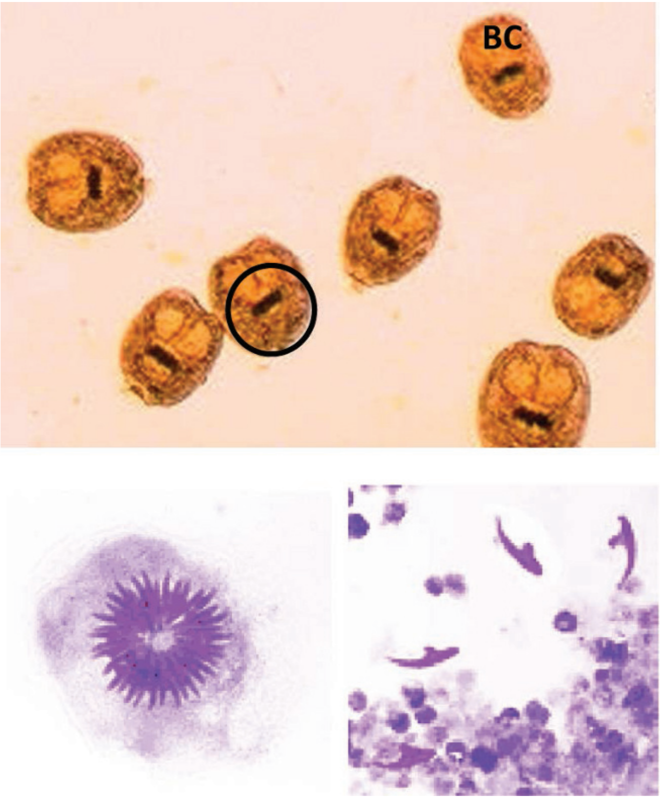

Figure 34.49 *Echinococcus granulosus*. (Upper) Brood capsules (BC); the dark areas represent the hooklets on the protoscolices (circle). (Lower) Hooklets stained with the Ryan modified trichrome/blue. (Courtesy of Norbert Ryan.) doi:10.1128/9781555819002.ch34.f49

fects the organ distribution of the cysts. Multiorgan involvement seems to be on the rise in children.

Hydatid cysts should be considered in patients with abdominal masses with no clearly defined diagnosis. Although eosinophilia is present in 20 to 25% of patients, it is merely suggestive. Many asymptomatic cysts are first discovered after radiologic studies. The cyst usually has a well-defined margin with occasional fluid level markings. These studies can also be helpful in diagnosing osseous involvement. Scans may also demonstrate a space-occupying lesion, particularly in the liver. If the cyst is large and located in the abdomen, a thrill is sometimes detected.

Echinococcus multilocularis Hydatid Disease (Alveolar Disease)

Although the alveolar form of hydatid disease has been found in other tissues (eye, bone, lung, peritoneum, adrenals, brain, ovary, lymph nodes, prostate, gallbladder, pancreas, spleen), the liver is the most common site. The disease may resemble a slowly growing carcinoma, may cause symptoms of intrahepatic portal hypertension, and may spread to other sites via metastatic dissemination. In humans there are several stages of the infection; they have been described as initial, progressive, advanced, stable, and abortive.

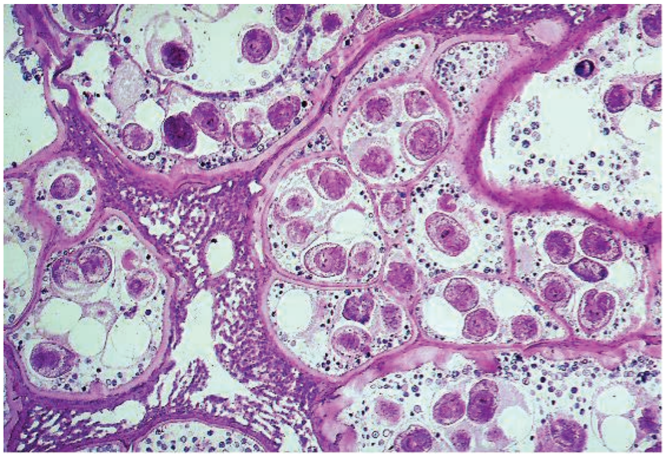
Proliferation of the cyst is most active at the advancing margin, while the interior of the cyst structure may deteriorate and appear to be a necrotic abscess filled with pus. Since the human is not a normal host, the typical brood capsules, protoscolices, and calcareous corpuscles may not develop (Fig. 34.50). In humans, the laminated membrane may surround vesicles that are void of protoscolices and other internal structures. The lesions caused by *E. multilocularis* may appear as firm, solid, cancer-like masses, and the outer layer has a poorly defined margin that continues to grow and spread throughout the tissue. In tissue sections, homogeneous, thin cystic structures of various dimensions are strongly PAS positive. Mucoid material within the cystic structures is also PAS positive. Wide coagulative necrosis is seen, as well as foreign-body-type giant cells appear at the periphery of the lesion in some cases. Necrotic ground, mucoid globules, and PAS-positive hyaline cuticular structures are evident in cytologic smears; some smears also demonstrate foreign body-type giant cells.

In a case where the patient presented with a multicystic mass in the pancreas, fine-needle aspirate biopsy revealed some protoscolices, free hooklets, and fragments of the laminated layer, findings which are pathognomonic for echinococcosis.

Taenia (*Multiceps*) spp. (*Taenia multiceps*, *Taenia serialis*) (Coenurosis)

Although the adult tapeworms resemble *Taenia* spp., the larval form is a coenurus, a unilocular cyst with the same

Figure 34.50 *Echinococcus multilocularis*. Numerous vesicles in tissue; H&E stain. Note there is no single limiting membrane, as occurs in *E. granulosus* hydatid cysts. This growth tends to mimic a metastatic cancer. doi:10.1128/9781555819002.ch34.f50



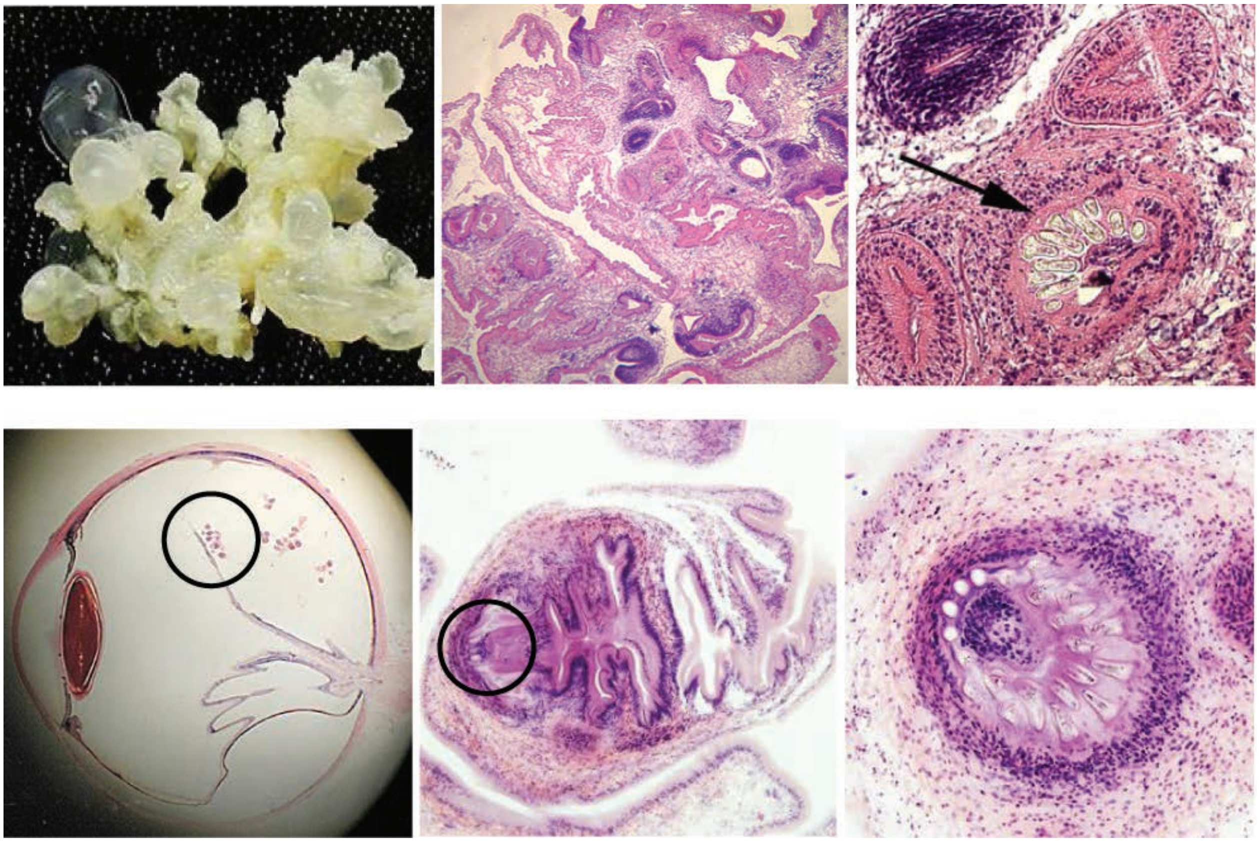


Figure 34.51 (Upper row) Coenurus (*Taenia multiceps*, *T. serialis*) removed from a subcutaneous nodule in the shoulder. (Left) Gross specimen. (Middle) Cross section. Although the species was not identified in this case, the pathology is consistent with *T. serialis*. (Right) Higher magnification (200×) of the same specimen shown on the left. The black arrow points to hooklets in one of the protoscolices. (Lower row) Coenurus from a human eye. (Left) *Taenia* species with multiple protoscolices (circle); no daughter cysts develop in a coenurus. (Middle) Higher magnification of one of the protoscolices; note the hooklets (circle). (Right) High magnification of the protoscolex showing multiple hooklets. (Courtesy of the CDC Public Health Image Library.) doi:10.1128/9781555819002.ch34.f51

configuration as a cysticercus but containing multiple scolices. Human cases have been reported worldwide; however, identification to the species level is often very difficult if not impossible (Fig. 34.51). In humans, fewer than 175 cases have been reported. Most coenuri have been located in the brain or spinal cord, but they can also be found in the subcutaneous tissues. Symptoms have been those associated with any space-occupying lesion, including headache, vomiting, paraplegia, hemiplegia, aphasia, seizures, and eye symptoms (if the coenurus is present in the eye).

Metacestodes (coenuri) are usually thin-walled, white or gray, spherical or ovoid polycephalic cysts, measuring from a few millimeters to 6 cm. A coenurus contains gray or white jelly-like fluid and multiple yellow-white protoscolices. The numerous protoscolices distinguish a coenurus from a cysticercus, which contains a single protoscolex. Coenuri may be multilocular, but most are unilocular.

The body wall varies from 50 to 150 μm and is composed of a tegument, muscle cells, and tegument cells. On the surface of the tegument are fine, hair-like structures called microtriches or microvilli, 1 to 2 μm long. The microvilli form a border that completely covers the outer surface of the cyst wall and the invaginated surface of each protoscolex (4).

Spirometra mansonoides and *Diphyllobothrium* spp. (Sparganosis)

The larval forms (spargana) of *Spirometra mansonoides* and *Diphyllobothrium* spp. were first recognized in humans from tissues removed at autopsy. In areas where infections are endemic, similar forms can be found in the subcutaneous connective tissue and between the muscles in frogs, lizards, snakes, birds, and certain mammals. When these spargana are fed to the definitive hosts (dogs and cats), adult tapeworms of several related species of *Spi-*

rometra develop. The general name for these spargana is *Spirometra mansonoides*. Although cases have been reported worldwide, sparganosis is most common in China, Japan, and Southeast Asia.

Human infection can occur from (i) ingestion of infected *Cyclops* spp. (the procercoid stage penetrates the intestinal wall, migrates into tissues, and develops into the sparganum), (ii) ingestion of raw infected flesh of one of the second intermediate hosts (fish, snakes, amphibians, and mammals), or (iii) local application of raw, infected flesh of one of the second intermediate hosts to the skin, conjunctiva, or vagina (the spargana migrate from vertebrate host tissues into human tissue). The spargana are white, ribbonlike worms measuring from a few millimeters to several centimeters long. Human infections with spargana are classified into two forms, nonproliferative sparganosis and proliferative sparganosis (aberrant spargana).

The sparganum is a wrinkled, white, ribbon-shaped organism, 3 mm in width and up to 30 cm long. It is a solid-bodied larva that has no bladder and has bothrids (two longitudinal grooves) at the anterior end instead of suckers (similar to the scolex of *Diphyllobothrium latum*). The larva has an unsegmented strobila 20 to 30 cm in length, bundles of longitudinal muscle fibers scattered throughout the mesenchyme, and a thick tegument (Fig. 34.52).

Most patients have slowly growing, tender, subcutaneous nodules. These nodules may also be migratory. Ocular sparganosis is accompanied by pruritus, pain, lacrimation, and edematous swelling of the eyelid (which may look much like Romaña's sign in Chagas' disease). Depending on the location of the sparganum, there may be elephantiasis (lymph channels), peritonitis (intestinal perforation), or brain abscess. Most patients have leukocytosis and eosinophilia. The sparganum has been reported to live for more than 9 years.

The more elongate, wormlike structure of the sparganum can usually be distinguished from the bladder structure of a cysticercus or coenurus, since the last two have suckers and hooklets, both of which are lacking in a sparganum. The parasites are usually recovered alive and are approximately several centimeters in length. They are glistening white and opaque, they resemble narrow tapeworm proglottids, and they are motile, similar to the motility seen with a *Taenia saginata* proglottid.

Trematodes

Schistosoma mansoni, *S. japonicum*, *S. mekongi*, *S. malayensis*, *S. haematobium*, *S. intercalatum* (Blood Flukes)

Schistosoma parasites are blood flukes that infect an estimated 200 million people worldwide (Fig. 34.53 and 34.54). In chronic infection with *Schistosoma*, the severe pathology, including liver fibrosis and splenomegaly, is

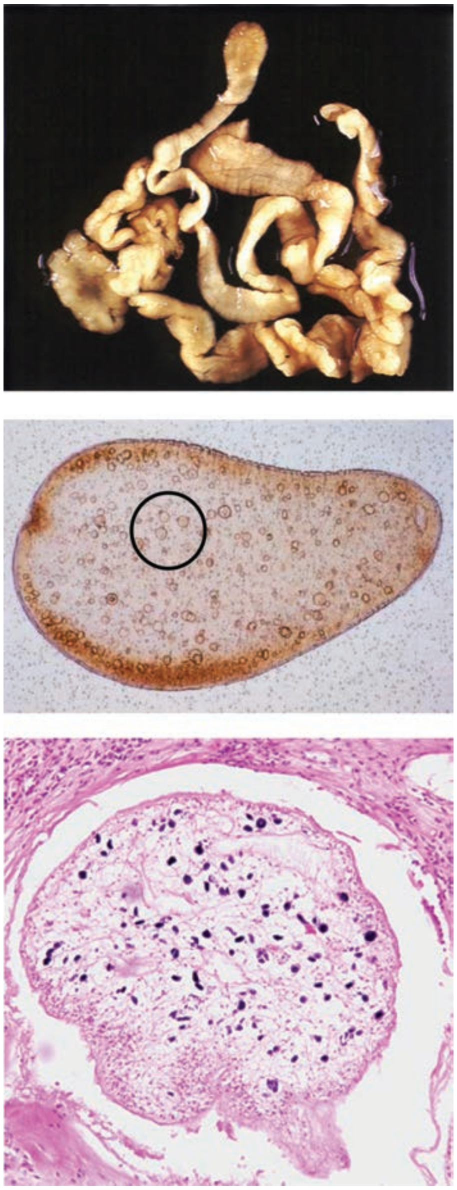

Figure 34.52 *Spirometra* sparganum larva. (Top) Spargana are larval forms of various tapeworms in the genus *Spirometra*. Spargana are white and ribbonlike in shape, range from a few millimeters to >30 cm in length, and are actively motile. The solid sparganum lacks suckers and bladder walls; there are irregular bundles of muscle fibers, typical folded tegument, and calcareous corpuscles in the parenchyma (Armed Forces Institute of Pathology photograph). (Middle) *Spirometra mansonoides* sparganum; note the calcareous corpuscles, which are refractile sand-like particles in the parenchyma (circle) (courtesy of R. E. Pugh, http://parasite.org.au/pugh-collection/Spirometra-%20mansonoides%204%2021.jpg_Index.html). (Bottom) Proliferating sparganum in groin tissue of a patient from Paraguay; H&E (courtesy of the CDC Public Health Image Library). doi:10.1128/9781555819002.ch34.f52

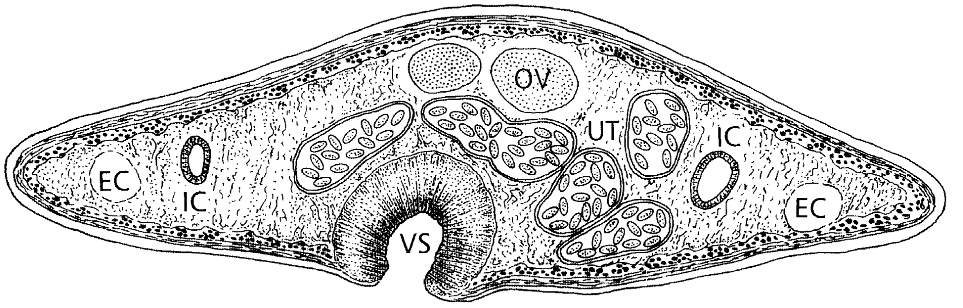

Figure 34.53 Diagram of the cross section of a trematode. Note the coiled uterus (UT) containing eggs, the lobed ovary (OV), intestinal ceca (IC), and excretory canals (EC). Also, note the large ventral sucker (VS). (Illustration by Sharon Belkin.) doi:10.1128/9781555819002.ch34.f53

caused by the immune response to the parasite eggs rather than the parasite itself (Fig. 34.55, 34.56, and 34.57). One of the clinical manifestations of helminth infection is the presence of type 2 granulomas. The lung is the primary site of organ involvement in a range of granulomatous conditions. The immune response to *Schistosoma mansoni* eggs in mice results in the development of hepatic, intestinal, and pulmonary granulomas that lead to extensive fibrosis. The cellular composition of the granulomas includes eosinophils, alternatively activated (M2) macrophages, lymphocytes, neutrophils, mast cells, and fibroblasts. Further, the recruitment and migration of these cells into the site of inflammation are controlled by cytokines and chemokines. Granulomas vary in structure; some eggs are surrounded by an eosinophilic material, the Splendore-Hoeppli phenomenon. Immature and dead eggs provoke little to no response.

Schistosome eggs are highly immunogenic. Within infected hosts, eggs induce vigorous immune responses and are rapidly surrounded by inflammatory cells, creating a granuloma. Neutrophils are believed to play a significant role in *Schistosoma japonicum* granulomatous pathology. In the initiation of granuloma formation, neutrophils are recruited to the core of the granuloma, leading to a neutrophil-mediated inflammatory response which ultimately causes tissue damage. At a later stage, neutrophils are recruited again and accumulate at the periphery of the granuloma, where they release a number of granule proteins involved in collagen degradation and reabsorption. It is well known that granuloma formation is a T-cell-mediated immune response. The T-cell-mediated response, especially CD4$^+$ T-cell response, has been reported to participate in neutrophil induction in schistosomiasis.

Eggs of *S. haematobium* and *S. japonicum* often become calcified and surrounded by hyalinized scar tissue. While alive in the veins, adult worms provoke no host response; however, if they die, the dead worms cause large focal lesions. In some patients with *S. mansoni* infection, eggs may be numerous in the mucosa, lamina propria, and submucosa. Many eggs laid in the mesenteric venules are

Figure 34.54 (Left) Diagram of male and female *Schistosoma* trematodes. The female worm is lying with the male worm *in copulo*. doi:10.1128/9781555819002.ch34.f56

carried into the intrahepatic portal circulation. The granulomas formed can result in marked portal fibrosis.

It is important to remember that if *S. haematobium* eggs are seen in urine, some may be in the process of hatching and some may have already hatched, releasing the miracidium larvae (Fig. 34.57).

Paragonimus spp. (Lung Fluke)

Paragonimus westermani is found in Asia, *Paragonimus mexicanus* is an important human pathogen in Central and South America, and *Paragonimus kellicotti* infections are found in North and South America. Most paragonimiasis infections are caused by *P. westermani*. A number of other species are thought to infect humans. Humans are infected by ingesting uncooked crabs or crayfish containing metacercariae. The metacercariae excyst in the duodenum and migrate through the intestinal wall into the abdominal cavity. The larvae migrate around or through the diaphragm into the pleural cavity and the lungs and mature to adults in the vicinity of the bronchioles, where they discharge their eggs into the bronchial secretions.

Migration of the larval forms through the intestinal wall into the abdominal cavity is generally not associated with any significant pathologic changes or symptoms. If the larvae remain in the abdomen, some patients may have abdominal pain, intra-abdominal masses, tenderness, fever, diarrhea, nausea, vomiting, and eosinophilia. Once the larvae have reached the peritoneal cavity, they begin to migrate through organs and tissues, producing localized hemorrhage and leukocytic infiltrates.

When the worms finally reach the lungs and mature, a pronounced tissue reaction occurs, with infiltration of eosinophils and neutrophils. A fibrotic capsule forms around the worm. The cysts contain purulent fluid with flecks or “iron filings” composed of brownish yellow eggs. Many of the cysts perforate into the bronchioles, releasing their contents of eggs, necrotic debris, metabolic by-products, and blood into the

(Lower) *Paragonimus* sp. from lung biopsy; H&E. Eggs measured 80 to 90 µm by 40 to 45 µm, but were not identified to species. (Courtesy of the CDC Public Health Image Library.) doi:10.1128/9781555819002.ch34.f58

respiratory tract. The eggs may also enter the pulmonary tissue, or they may be carried by the circulatory system to other body sites, where they cause a granulomatous reaction (Fig. 34.58).

Symptoms of paragonimiasis depend largely on the worm burden of the host and are usually insidious in onset and mild in patients with chronic infections. Light infections may be asymptomatic, although peripheral blood eosinophilia and lung lesions may be noted on X-ray examination. As the cysts rupture, a cough develops, with increased production of viscous blood-tinged sputum (rusty sputum, which may have a foul fish odor) and increasing chest pain.

Larval forms may end up in many ectopic sites other than the lungs and have been detected in the liver, intestinal wall, muscles, peritoneum, and brain. The most serious consequences of paragonimiasis are the cerebral complications, which are commonly found in younger age groups. Unlike adult flukes in other extrapulmonary sites, worms found in the brain usually contain eggs. The worms probably migrate from ruptured lung cysts and travel through the soft tissues surrounding veins into the brain area. The worms eventually encapsulate, but before being walled off they cause necrosis within the brain tissue, as well as possible cerebral hemorrhage, edema, and meningitis.

Skull radiographs generally reveal round or oval cystic calcifications; they have been described as looking like bubbles. CT scans reveal multilocular cysts with edema, migration tracks, peripheral density, bronchial wall thickening, and centrilobular nodules; ring enhancement may be visible after the use of contrast (chapter 19, Fig. 19.19). MRI demonstrates areas of granulomatous inflammation surrounding the lesions; MRI of the brain may reveal multiple conglomerated iso- or low-signal-intensity round nodules with peripheral rim enhancement. In the liver, CT and MRI images may reveal a cluster of small cysts with rim enhancement in the subcapsular area. This finding seems to be characteristic for hepatic paragonimiasis. Solitary nodular lesions can often mimic lung cancer, tuberculosis, or fungal diseases. Three characteristic findings are seen with cerebral paragonimiasis: arachnoiditis, encapsulated abscesses, and granulomas that may calcify.

Fasciola spp. (Sheep Liver Fluke)

This infection is an important health problem, particularly in the Andean countries of Peru, Bolivia, and Chile. Humans are infected by ingestion of uncooked aquatic vegetation on which metacercariae are encysted. Metacercariae excyst in the duodenum and migrate through the intestinal wall into the peritoneal cavity. The larvae enter the liver by penetrating the capsule (Glisson's capsule) and wander through the liver parenchyma for up to 9 weeks. The larvae finally enter the bile ducts, where they mature and produce eggs, which are passed out in the feces. The adult worms can attain a length of 30 mm and a width of about 13 mm and can live for more than 10 years.

In the acute phase, symptoms may be present over a period of weeks to months and include dyspepsia, fever, right upper quadrant pain, anorexia, hepatomegaly, splenomegaly, ascites, urticaria, respiratory symptoms, and jaundice. Metacercarial larvae do not cause significant pathologic damage until they begin to migrate through the liver parenchyma (Fig. 34.59). The amount of damage depends on the worm burden of the host. Linear lesions of 1 cm or greater can be found. Hyperplasia of the bile ducts occurs, possibly as a result of toxins produced by the larvae. Symptoms associated with this migratory phase have included fever, epigastric and right upper quadrant pain, intestinal complaints, and urticaria, although other patients remain asymptomatic. Asymptomatic infections appear to be more common in Peru. Other symptoms include loss of appetite, flatulence, nausea, diarrhea, and a nonproductive cough. Patients may also have hepatomegaly, splenomegaly, ascites, chest signs, and jaundice. Leukocytosis, eosinophilia, and mild to moderate anemia are found in many patients.

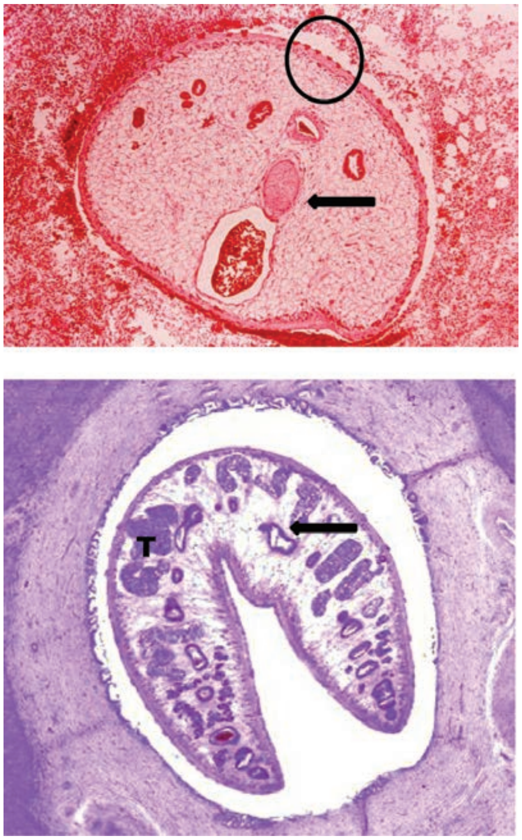

Figure 34.59 (Upper) Adult *Fasciola hepatica* embedded in the intestinal wall. The parasite presents as an oval to round mass limited by a spined cuticle (circle). The parasitic parenchyma is punctuated by multiple sections through the gut. The two centrally located tubular structures, separated by a light-staining muscular sucker (arrow), are part of the reproductive apparatus of the parasite. A marked inflammatory response is present in the adjacent host tissues, and fresh RBCs can be seen near the parasite. (Lower) Adult *F. hepatica* in the liver. Note that the intestinal ceca (arrow) and portions of the testes are clearly visible (T). (From *A Pictorial Presentation of Parasites*: a cooperative collection prepared and/or edited by H. Zaiman; photograph courtesy of B. C. Walton.)
doi:10.1128/9781555819002.ch34.f59

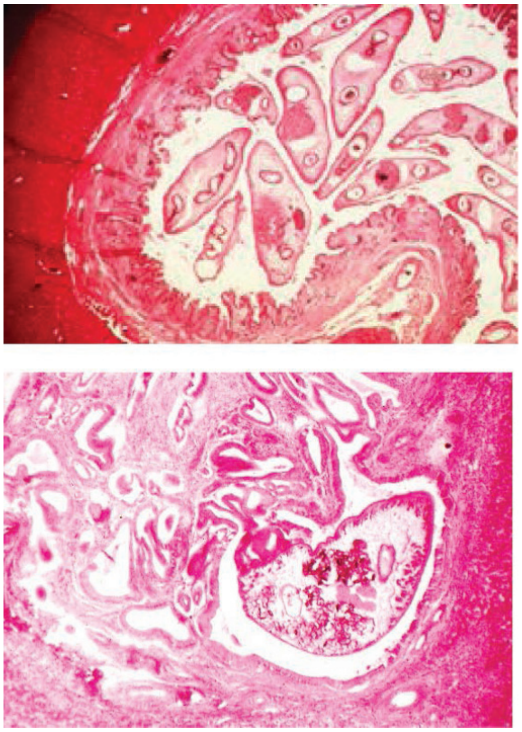
In the chronic phases, the patient has few to no symptoms once the flukes have lodged in the biliary passages. However, there may be some epigastric and right upper quadrant pain, diarrhea, nausea, vomiting, hepatomegaly, and jaundice. If the flukes are found in the extrahepatic biliary ducts, symptoms may mimic those seen in cholelithiasis. In the chronic phase, there tend to be some liver function abnormalities, as well as eosinophilia. Larvae may be found in ectopic foci after penetrating the peritoneal cavity. Worms in human infections have been discovered in many areas of the body other than the liver. Other body sites include the intestinal wall, lungs, heart, brain, and skin. Symptoms mimic those seen with VLM and include vague abdominal pain. Unfortunately, surgery may be required to determine the exact cause of the symptoms.

Once the worms have established themselves in the bile ducts and matured, they cause considerable damage from mechanical irritation and metabolic by-products as well as obstruction. The infection produces hyperplasia of the biliary epithelium and fibrosis of the ducts with portal or total biliary obstruction. The gallbladder undergoes similar pathologic changes and may even harbor adult worms. Adult worms may reinvade the liver parenchyma, producing abscesses. Symptoms and signs of infection during the late stages after egg production has begun are those associated with biliary obstruction and cholangitis. Acute epigastric pain, fever, pruritus, jaundice, hepatomegaly, and eosinophilia are common.

Clonorchis sinensis (Chinese Liver Fluke)

Humans become infected by ingesting the metacercariae in raw or incompletely cooked fish. Metacercariae excyst in the duodenum, enter the common bile duct, and travel to the distal bile capillaries, where the worms mature over a period of about a month (Fig. 34.60). The life cycle takes approximately 3 months to complete in humans. Most patients with mild infections of fewer than 100 flukes have few symptoms, which may include general malaise, abdominal discomfort, and diarrhea. In 10 to 40% of patients, peripheral eosinophilia occurs with fluctuating obstructive jaundice. Moderate infections with fewer than 1,000 worms include symptoms of fever and chills, fatigue, anorexia, diarrhea, weight loss, discomfort, and abdominal distention. In severe disease with up to 20,000 flukes, an additional symptom may include acute right upper quadrant pain. In the late stage of severe cases, jaundice, diarrhea, portal hypertension, hepatosplenomegaly, ascites, and edema can occur.

Figure 34.60 *Clonorchis sinensis*. (Upper) Cross sections of adult flukes within the bile duct, which shows marked hyperplasia of epithelium. (Lower) Adult fluke in bile duct, larger magnification. (From *A Pictorial Presentation of Parasites*: a cooperative collection prepared and/or edited by H. Zaiman.)
doi:10.1128/9781555819002.ch34.f60



In general, complications result from biliary obstruction. As the worms mature in the distal bile ducts, an inflammatory response is seen in the biliary epithelium. The extent of pathologic changes is related to the intensity and duration of infection. The lesions are confined mainly to the biliary system and are the result of mechanical irritation and toxins produced by the worms. In light infections, there appears to be little or no change in liver parenchyma, whereas heavy infections cause thickening and localized dilations of the bile ducts with hyperplasia of the mucinous glands. As a result, the biliary tract may become obstructed, causing bile retention, infiltration of lymphocytes and eosinophils, and fibrosis. The adenomatous changes may persist for many years in patients with light infections. The infections have been associated with obstructive jaundice, which may be aggravated by biliary stones and liver abscesses. Many patients infected with *Clonorchis sinensis* have recurrent pyogenic cholangitis. There is no direct evidence that infection with *C. sinensis* causes chronic bacterial infection. Acute pancreatitis, cholecystitis, and cholelithiasis may be the result of worm invasion. Cirrhosis is probably related to malnutrition rather than parasitic infections. CT evaluation has shown that in the presence of diffuse mild intrahepatic bile duct dilation, enlargement of the body or tail (or both) of the pancreas, with a cluster of small cystic changes within the pancreatic parenchyma, provides strong evidence of *C. sinensis* pancreatitis.

C. sinensis has been linked to neoplasms of the bile duct and to cholangiocarcinoma, which is most frequently observed in areas where clonorchiasis is endemic. Cholangiocarcinoma is a malignant tumor that arises from the bile duct epithelium and is the second most prevalent liver cancer after hepatocellular carcinoma. The tumor usually occurs in patients 60 to 80 years of age and rarely in patients younger than 40 years. There appears to be no direct link between infection and carcinoma, although one of the first steps in malignant transformation may be induced by the biliary tract hyperplasia caused by the worms. Patients with primary sclerosing cholangitis (PSC) have a substantial predisposition for bile duct carcinoma. Although the exact mechanisms are not well defined, longstanding inflammation can lead to cholangiocarcinoma in patients with chronic *C. sinensis* infection. PSC is an uncommon disease, characterized by stricturing, fibrosis, and inflammation of the biliary tree, which is closely associated with chronic inflammatory bowel disease, particularly ulcerative colitis. The only effective treatment for PSC is orthotopic liver transplantation, which in the absence of cholangiocarcinoma has a 5-year survival rate of 89%. However, patients with cholangiocarcinoma who undergo liver transplantation have a high risk of recurrence and poor survival statistics.

Peripheral cholangiocarcinoma is usually seen as a large, well-defined hepatic mass with lobulated margins. CT and MRI reveal band-like peripheral contrast enhancement of variable thickness around the tumor during the early phase, with progressive filling of contrast material in the later stages. This appearance occurs through slow diffusion of contrast materials into the interstitial spaces of the tumor. Fibrosis within this type of cholangiocarcinoma also contributes to the delayed contrast enhancement of the tumor. Additional findings in peripheral cholangiocarcinoma include capsular retraction and dilatation of the peripheral intrahepatic ducts.

Most hilar and extrahepatic cholangiocarcinomas cause a focal stricture of the bile duct, whereas papillary carcinoma is occasionally found in the form of a polypoid mass within the duct. By thin-section CT, this tumor type can be seen as an ill-defined focal wall thickening. Using ultrasonography, the tumor can appear as a thickening or encircling mass along the bile duct wall. In a number of cases, the infiltrating tumor is seen by either ultrasonography or CT as a simple nonunion of the dilated right and left hepatic ducts without any identifiable mass. Cholangiography shows a focal or diffuse stricture or complete obstruction of the bile ducts; from this image the extent of the disease can be determined.

Radiological findings are regarded as pathognomonic for clonorchiasis because they demonstrate the unique pathological changes of this disease. Due to remarkable advances in imaging technology, individual flukes can now be seen by means of noninvasive radiological techniques.

Echinostoma spp.

A number of species of echinostomes have been reported to infect humans, including *Echinostoma hortense*, *E. ilocanum*, *E. macrorchis*, *E. perforiatum*, and *E. revolutum*. Most of the species are found in Asian countries; *E. ilocanum* is the most important species. These flukes are distinguishable from other trematodes by the distinctive horseshoe-shaped collar of spines on the lateral and dorsal sides of their oral sucker (Fig. 34.61) (4).

Adult worms are attached to the mucosal wall of the small intestine and lay eggs, which are passed from the intestinal lumen in the feces. The eggs are immature, ellipsoidal, yellow-brown, and operculated. They measure 86 to 116 μm by 58 to 69 μm. The miracidia take 1 to 2 weeks to mature in the environment before they hatch from the eggs and infect the snail intermediate host. Two or more generations of rediae are produced before cercariae develop. These cercariae encyst in freshwater mollusks, and humans are infected by eating these mollusks raw rather than cooked. The metacercariae hatch in the intestine, attach to the mucosal wall, and develop into mature adult worms.

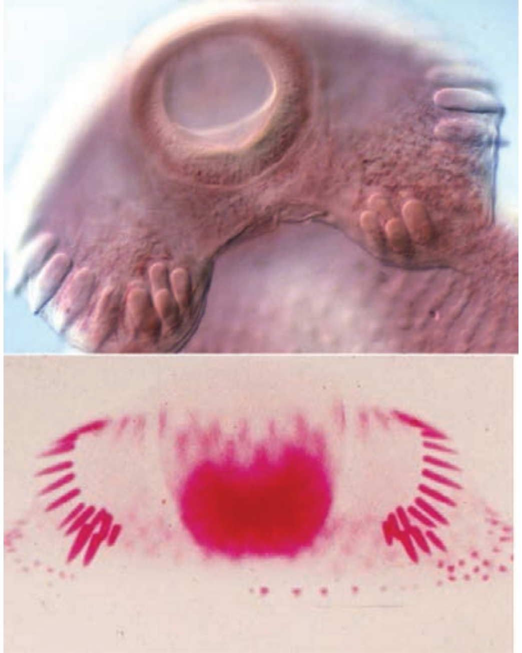


Figure 34.61 *Echinostoma* adult worm. (Upper) Stained adult worm characterized by having a circumoral disk with a crown of spines surrounding the small oral sucker (courtesy of www.k-state.edu). (Lower) Enlarged image of the crown of spines (surrounding the oral sucker). The living worm is reddish gray and measures 2.5 to 6.5 mm in length by 1 to 1.35 mm in width. (From *A Pictorial Presentation of Parasites*: a cooperative collection prepared and/or edited by H. Zaiman.)
doi:10.1128/9781555819002.ch34.f61

With light infections, the patient may be asymptomatic and the adult worms cause only minor problems other than localized inflammation. In heavy infections, the worms can produce catarrhal inflammation and mild ulceration and the patient may experience diarrhea and abdominal pain.

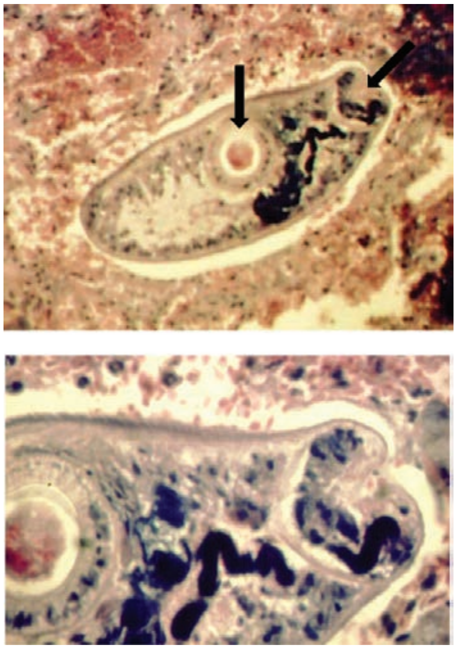
Eggs of *E. ilocanum* can be detected in the stool. They are the same size (some strains) and shape as the eggs of *Fasciola hepatica* and *Fasciolopsis buski*. Because of the overlap in size range, exact identification cannot be made from the eggs; therefore, the diagnosis may have to be made on the basis of patient history or clinical findings.

Alaria americana

Alaria americana is a trematode that is normally found in the intestines of wild mammalian carnivores such as wolves, foxes, raccoons, bobcats, and skunks. The eggs are passed in the stool, hatch in water, and invade freshwater snails of the genus *Helisoma*. Cercariae then leave the snail and infect frog tadpoles. The first case of disseminated human infection by the mesocercarial stage of this worm was found in a 24-year-old man in Canada who died 8 days after the onset of his illness. The infection was probably acquired through ingestion of inadequately cooked frogs, which serve as intermediate hosts for this parasite. The infection was diagnosed by lung biopsy, and mesocercariae were found in the stomach wall, lymph nodes, liver, myocardium, pancreas and surrounding adipose tissue, spleen, kidney, lungs, brain, and spinal cord at autopsy (Fig. 34.62). Apparently, there was no host reaction to the parasites. Granulomas were present in the stomach wall, lymph nodes, and liver, but no worms were recovered from these sites.

Two cases of eye infection with mesocercariae of *Alaria* were found in unrelated Asian men who had unilateral decreased vision. Both patients had pigmentary tracks in the retina, areas of active and/or healed retinitis, and other signs of diffuse unilateral subacute neuroretinitis. The worms were seen in the retinas and vitreous several years after the original infection was thought to have occurred. The probable source of infection was ingestion of undercooked frogs' legs containing the infective stage. In addition to the prolonged intraocular infection, the mesocercariae caused diffuse unilateral subacute neuroretinitis, a condition thought to be caused only by intraocular nematode larvae.

Note the oral and ventral suckers (higher magnification). (From *A Pictorial Presentation of Parasites*: a cooperative collection prepared and/or edited by H. Zaiman. Photograph courtesy of R. S. Freeman.) doi:10.1128/9781555819002.ch34.f62



Blood Parasites

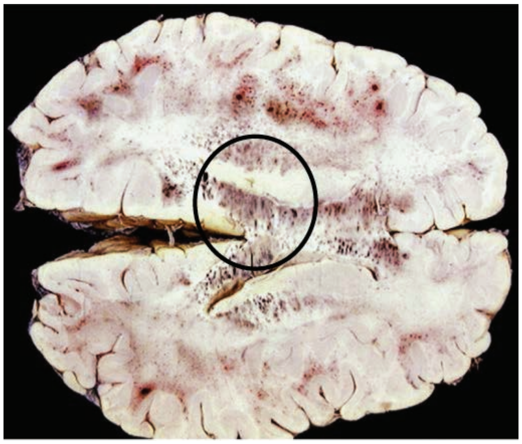
Malaria

Plasmodium spp. (Cerebral Malaria)

With the exception of tuberculosis, malaria kills more people than any other communicable disease in the world. Severe or fatal complications of *P. falciparum* malaria can occur at any time during the infection and are related to the plugging of vessels in the internal organs, with the symptoms depending on the organ(s) involved. The severity of the complications in a malaria infection may not correlate with the parasitemia seen in the peripheral blood, particularly in *P. falciparum* infections.

Cerebral malaria is most often seen in *P. falciparum* malaria, although it can occur in the other types as well (Fig. 34.63 and 34.64). If the onset is gradual, the patient may become disoriented or violent or may develop severe headaches and pass into coma. Some patients, even those who exhibit no prior symptoms, may suddenly become comatose. Physical signs of CNS involvement are quite variable, and there is no real correlation between the severity of the symptoms and the peripheral blood parasitemia. It has been shown that patients with cerebral malaria were infected with RBC rosette-forming *P. falciparum* and that plasma from these patients generally had no antirosetting activity. A rosette usually consists of a parasitized RBC surrounded by three or more uninfected RBCs. Interaction with adjacent uninfected RBCs in rosettes appears to be

Figure 34.63 Malaria. Section through the cerebrum showing more congestion of the white matter (petechial hemorrhages) than of the gray (circle). (Armed Forces Institute of Pathology photograph.) doi:10.1128/9781555819002.ch34.f63



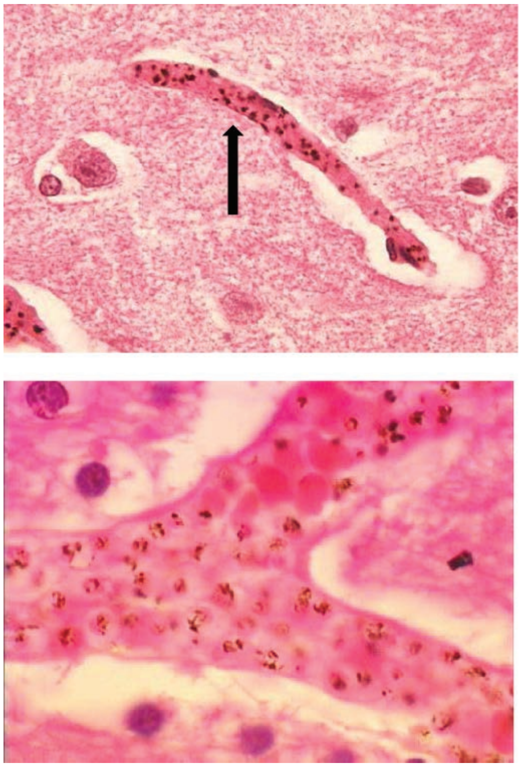


Figure 34.64 (Upper) Cerebral malaria showing cerebral capillaries congested with parasitized erythrocytes (arrow). Parasitized erythrocytes stick to the endothelium and occlude the capillaries. (Lower) Note the capillary containing parasitized erythrocytes; note the brownish malarial pigment (higher magnification). (Armed Forces Institute of Pathology photograph.) doi:10.1128/9781555819002.ch34.f64

mediated by knobs seen on the parasitized RBC. In contrast, *P. falciparum* parasites from patients with mild malaria lacked the rosetting phenotype or had a much lower rosetting rate. Also, antirosetting activity has been detected in the plasma of these patients. These findings strongly support the idea that RBC rosetting contributes to the pathogenesis of cerebral malaria while antirosetting antibodies offer protection against these clinical sequelae.

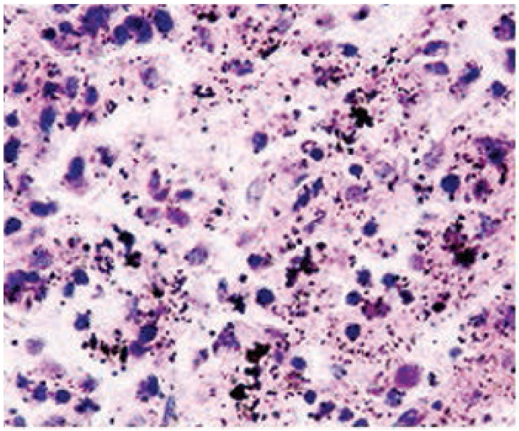

Figure 34.65 Malarial pigment present in the spleen. The spleen is enlarged to about 500 g during an acute attack; it is soft, diffusely pigmented, and congested and has rounded edges. The phagocytic cells lining the splenic sinuses contain malarial pigment, free parasites, and parasitized erythrocytes. During an acute attack, malarial pigment is evenly distributed throughout the spleen. doi:10.1128/9781555819002.ch34.f65

Signs and symptoms of cerebral malaria include headache, nuchal rigidity, altered levels of consciousness, seizures, ataxia, aphasia, and dysarthria. Because *P. falciparum* is the only malarial parasite that becomes sequestered in vessels, it is the only species of *Plasmodium* that has been seen in tissue sections. Malarial pigment is the end product of hemoglobin digestion into a porphyrin conjugated with a protein derived from the globin portion of hemoglobin. Malarial pigment and formalin pigment are morphologically very similar. Both appear microscopically as brown or black crystals that are birefringent under polarized light. However, they can usually be distinguished by certain general characteristics: malarial pigment appears as intracellular round granules. Postmortem findings of falciparum malaria usually include prominent generalized passive congestion. Grossly, there is often gray or brown discoloration of the brain, liver, and spleen caused by malarial pigment (Fig. 34.65).

Microscopically, masses of erythrocytes fill the lumen of small and medium-sized blood vessels, distending the vessels. Parasitized erythrocytes tend to lie against the endothelial surface of vessels. In a ring hemorrhage, a small vessel is occluded by parasitized erythrocytes, surrounded by necrotic parenchyma, and surrounded by hemorrhage of nonparasitized erythrocytes. In falciparum malaria, renal corticomedullary capillaries may contain parasitized erythrocytes. Pigment grains may be seen within glomeruli or phagocytic cells. In patients with oliguria, tubular necrosis and hemoglobin casts may be prominent.

Leishmania

Once leishmaniae have been carried to the bone marrow, spleen, and liver, a granulomatous cell-mediated immune response occurs that can result in subclinical disease and self-cure or in the clinical syndrome of visceral leishmaniasis. The incubation period usually ranges from 2 to 6 months; however, it can take a few days or weeks to several years. When giving a history, many patients do not remember having a primary skin lesion. In areas of endemic infection, the onset may be gradual, with vague symptoms and a general feeling of ill health. The onset in naive patients

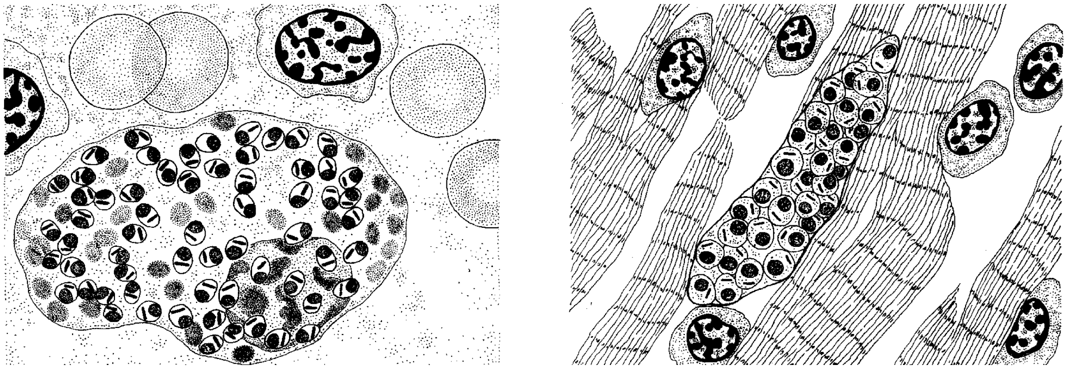

Figure 34.66 Diagram of amastigotes. (Left) *Leishmania donovani* amastigotes in a spleen smear. Each amastigote contains the dark, round nucleus and the bar-shaped kinetoplast. When cells are packed with amastigotes, often the complete morphology for each amastigote is not visible. (Right) *Trypanosoma cruzi* amastigotes in cardiac muscle. Each amastigote contains the nucleus (round, dark) and the kinetoplast (small bar). (Illustration by Sharon Belkin.) doi:10.1128/9781555819002.ch34.f66

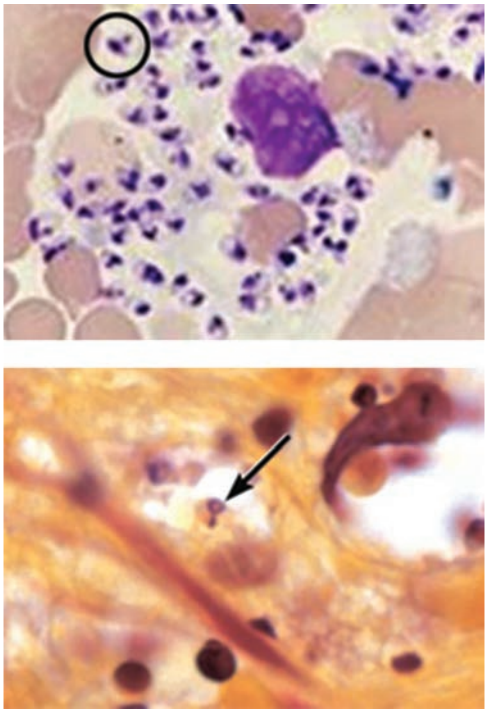
(migrants, soldiers, or travelers to areas of endemic infection) may be acute, with high fever, chills, anorexia, malaise, weight loss, and frequently diarrhea. This syndrome can easily be confused with typhoid fever, malaria, or other febrile illnesses caused by bacteria or viruses. Death may occur after a few weeks or several years. Generally, untreated visceral leishmaniasis leads to death; secondary bacterial and viral infections are also common in these patients.

The diagnosis of leishmaniasis can be difficult or sometimes impossible to confirm with standard Giemsa-stained smears. Because factors such as specimen quality, staining methods, and the skill of the microscopist can dramatically affect the sensitivity of this diagnostic procedure, a negative smear does not necessarily exclude a diagnosis of leishmaniasis (Fig. 34.66 to 34.68). In histologic sections, amastigotes stain well with H&E or Brown-Hopps modified tissue Gram stain. The Brown-Hopps stain creates the least amount of background staining and the strongest contrast from surrounding tissue, which makes identifying amastigotes much easier (1). Other stains sometimes used to identify amastigotes in tissue, including Giemsa, Wilder's reticulum, PAS, and immunoperoxidase stains, offer no advantage over the Brown-Hopps stain. Amastigotes in visceral leishmaniasis appear slightly smaller and less distinct than those observed in cutaneous leishmaniasis. Because kinetoplasts are much more difficult to identify, special stains such as Brown-Hopps and Wilder's reticulum are recommended.

Microscopically, liver sinusoids are dilated and show prominent amastigote-laden Kupffer's cells and little or no cellular reaction. Splenic aspiration is the surest method of parasitologic diagnosis, but carries the risk of splenic laceration. Careful observation of the patient after the procedure is essential. Giemsa-stained splenic smears demonstrate amastigotes in 98 to 100% of patients, and quantitation of splenic smears is helpful in measuring response to

Figure 34.67 *Leishmania* spp. (Upper) Smear of bone marrow showing many intracellular and extracellular *Leishmania* organisms. The amastigotes (Leishman-Donovan bodies) (circle) appear larger in smears than in tissue sections. The nucleus (longer dark object within the circle) and kinetoplast (smaller dark object within circle) are distinct in these organisms. (Lower) Single amastigote in the dermis (arrow) stained with Brown-Hopps tissue Gram stain. Note spherical nucleus and rod-shaped kinetoplast (Armed Forces Institute of Pathology photograph). doi:10.1128/9781555819002.ch34.f67



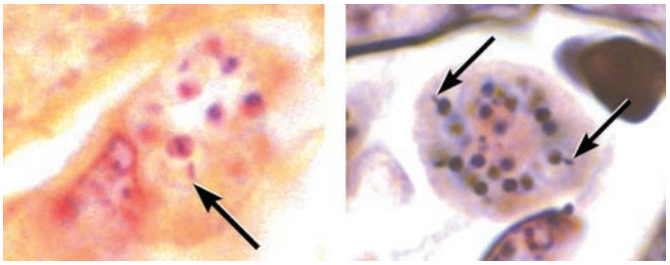


Figure 34.68 *Leishmania donovani*. (Left) Section of liver showing dilated sinusoids and greatly enlarged Kupffer cells (arrow); Brown-Hopps tissue Gram stain. (Right) Numerous black amastigotes in Kuppfer's cells; note kinetoplasts (arrows); Wilder's reticulum stain. (Armed Forces Institute of Pathology photographs.) doi:10.1128/9781555819002.ch34.f68

therapy. Promastigotes can be seen within 2 to 7 days in Schneider's medium or 7 to 21 days in Novy-MacNeal-Nicolle (NNN) medium after incubation at 25°C. For clinicians unfamiliar with splenic aspiration or concerned about its risks, there are satisfactory alternatives. Bone marrow smears usually contain amastigotes, though fewer than in splenic smears; parasites are found in up to 85% of patients.

Trypanosomes

Trypanosoma cruzi (American Trypanosomiasis, Chagas' Disease)

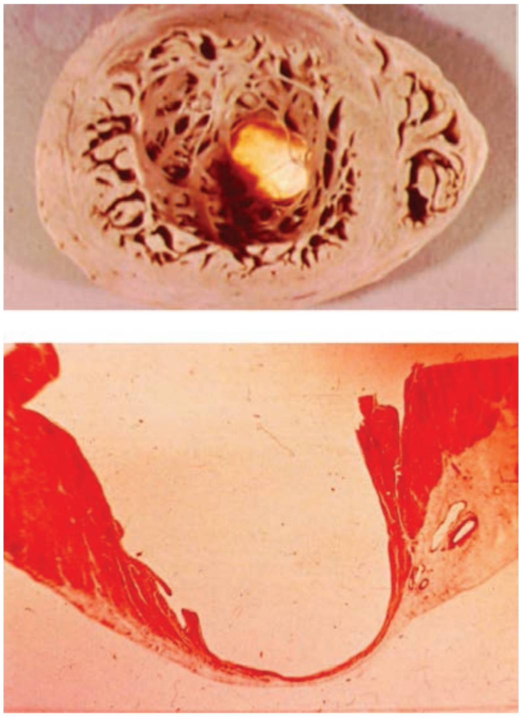
The disease is transmitted to humans through the bite wound caused by reduviid bugs (triatomids, kissing bugs, or conenose bugs). Humans are infected when metacyclic trypomastigotes are released with the feces while the insect is taking a blood meal and the feces are rubbed or scratched into the bite wound or onto mucosal surfaces such as eyes or mouth, an action stimulated by the allergic reaction to the insect's saliva. The organisms can also be transmitted as congenital infections, by blood transfusion, or by organ transplantation. On entry into the body, the metacyclic forms invade local tissues, transform to the amastigote stage, and begin to multiply within the cells. The local inflammatory process continues, forming the primary lesion, the chagoma, which blocks the lymphatic capillaries and causes edema.

On invasion of a cell, the trypomastigote loses its flagellum and undulating membrane and divides by binary fission to form an amastigote. The amastigote continues to divide and eventually fills and destroys the infected cell. Both amastigote and trypomastigote forms are released from the cell. The amastigote is indistinguishable from those found in leishmanial infections. It is 2 to 6 μm in diameter and contains a large nucleus and rod-shaped kinetoplast that stains red or violet with Giemsa stain. The cytoplasm stains blue. Only the trypomastigotes are found free in the peripheral blood.

Chronic Chagas' disease may develop years or decades after undetected infection or after the diagnosis of acute disease. The most frequent clinical sign of chronic Chagas' disease in 25 to 30% of patients is cardiomyopathy manifested by cardiomegaly and conduction changes. This may present as congestive heart failure, thromboembolic phenomena, cardiac arrhythmias, and sudden death. Cardiac pathology includes mononuclear inflammatory infiltrate, focal myocarditis, epicarditis, and neuroganglionitis, associated with variable focal fibrosis and widely variable autonomic dysfunction. Apparently, the immune inflammatory response causes the autonomic dysfunction, which may lead to life-threatening arrhythmias and sudden death (Fig. 34.69 and 34.70).

Microscopically, there is marked interstitial fibrosis of the myocardium and rare amastigotes, with focal infiltrates of lymphocytes, monocytes, and plasma cells in which multinucleated giant cells are occasionally present. Focal accumulations of neutrophils and an occasional eosinophil may also be found. Apical lesions regularly appear as segments of acellular fibrous tissue associated with epicardial vessels and adipose tissue (13).

Figure 34.69 *Trypanosoma cruzi*. (Upper) Transillumination of apex highlights the apical aneurysm. (Lower) The thinned ventricular wall shows muscle fiber loss and fibrosis most prominent near the aneurysm. (From *A Pictorial Presentation of Parasites*: a cooperative collection prepared and/or edited by H. Zaiman.) doi:10.1128/9781555819002.ch34.f69



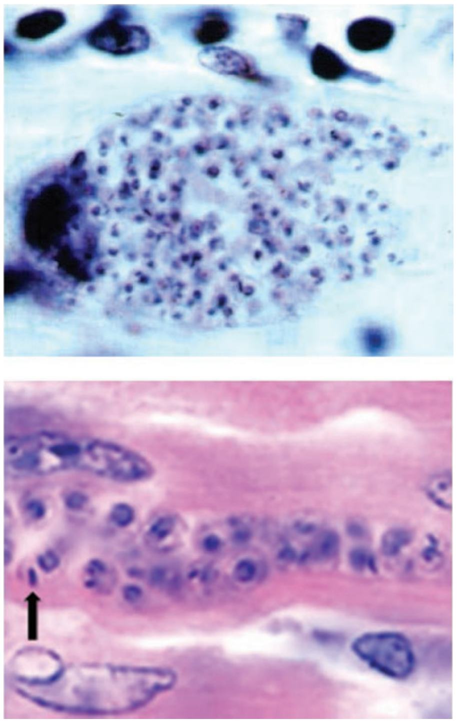


Figure 34.70 *Trypanosoma cruzi*. (Upper) Amastigotes in cardiac tissue. Note that many organisms are present; however, it is difficult to see differentiation between the nuclei and kinetoplasts. (Lower) Higher magnification of the amastigotes in cardiac muscle; note one of the kinetoplasts (looks like a small bar) (arrow). doi:10.1128/9781555819002.ch34.f70

Filaria

Wuchereria bancrofti

Infective larvae enter the skin of the human through the mosquito puncture wound when a blood meal is taken. The infective larvae enter the peripheral lymphatic system and migrate to lymph vessels distal to the lymph nodes, where they grow to mature female and male adults and mate. Thousands of developing embryos can be found within the uteri of the female. Microfilariae are released from the gravid female and can be detected in the peripheral circulation in 8 to 12 months postinfection; however, filariasis without microfilaremia is not uncommon.

Adult worms are minute and threadlike, have a smooth cuticle, and are found in the lymph nodes and lymphatic channels. Adult males are about 40 mm long by 0.1 mm in diameter. Adult females are 80 to 100 mm long by 0.24 to 0.30 mm in diameter. To perpetuate their life cycle, sheathed microfilariae invade the blood; sometimes they can also be found in hydrocele fluid and chylous urine. The microfilariae range from 244 to 296 µm long and actively move about in the lymph or blood. The microfilaria has a sheath, and the body nuclei do not extend to the tip of the tail.

Early symptoms of filariasis include high fevers (filarial or elephantoid fever), lymphangitis, and lymphadenitis. Filarial fever usually begins with a high fever and chills that last 1 to 5 days before spontaneously subsiding, and in many cases, patients with filarial fevers do not have a microfilaremia. The lymphangitis extends in a distal direction from the affected nodes where the filarial worms reside.

Lymphadenitis and lymphangitis develop in the lower extremities more commonly than in the upper. However, in some areas of endemic infection such as northeastern Brazil, factors other than filarial worms can be the cause of subclinical pathology of the leg lymphatics and are not specific for bancroftian filariasis. In addition to limbs, there can be genital (almost exclusively a feature of *W. bancrofti* infection) and breast involvement. The lymph nodes most often affected are the epitrochlears and femorals. The nodes are firm, discrete, and tender and tend to remain enlarged, while the lymph vessel is indurated and inflamed. The overlying skin is tense, erythematous, and hot, and the surrounding area is edematous. Occasionally, abscesses form at the lymph node or along the lymphatic system and may take 2 to 3 months to heal.

In lymphatic vessels that harbor the worms, an inflammatory reaction includes the infiltration of plasma cells, eosinophils, and macrophages in and around the affected vessel. Repeated inflammatory attacks lead to hyperplasia of the endothelium in addition to cellular infiltration. There is an increase in hydrostatic pressure resulting from the damage to the lymph vessel, which causes an increase in vessel wall permeability. The chronic leakage of fluid containing high levels of protein into the surrounding tissues (lymphedema) results in the hard or brawny edema, with thickening and verrucous changes in the skin, also known as elephantiasis (Fig. 34.71). Histologic examination of the skin shows hyperkeratosis and acanthosis, with scarring and a loss of dermal elasticity. Regional lymph nodes proximal to the worms eventually become fibrotic, and the proximal lymph vessels become stenotic and obstructed, leading to the development of collateral lymph channels. Elephantoid tissue is a mixture of lymph and fat in a matrix of fibrotic tissue.

Onchocerca volvulus (River Blindness)

Onchocerca volvulus L3 larvae are transmitted by black flies and develop into adults that are found in subcutaneous nodules. Adult female and male worms lie within fibrous tissue capsules in the dermis and subcutaneous tissues. The female adult is very long and thin, measuring up to 50 cm by 0.3 mm, while the adult male is 2.5 to 5 cm by 125 to 200 µm. Gravid females produce from 1,000 to 3,000 microfilariae per day, which invade the subcutaneous tissues, skin, and eyes.

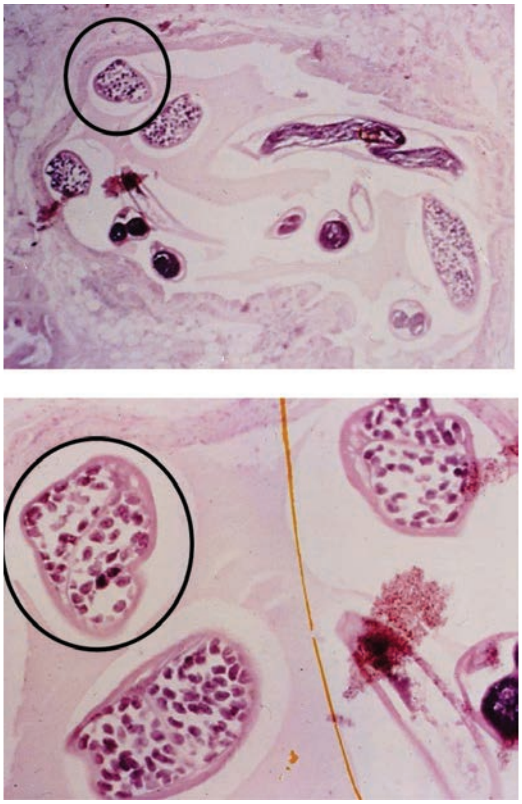

Figure 34.71 *Wuchereria bancrofti.* (Upper) Multiple sections of the worm in a dilated lymphatic vessel. Note the thin, threadlike structures *in utero* (circle). Various lengths are seen, depending on the actual tissue cut. Although these helminths are nematodes, they are shown with the blood parasites, since blood is the primary specimen for diagnostic purposes. (Lower) At higher power, the developing microfilariae *in utero* (circle) and cuticle are seen. (From *A Pictorial Presentation of Parasites*: a cooperative collection prepared and/or edited by H. Zaiman.) doi:10.1128/9781555819002.ch34.f71

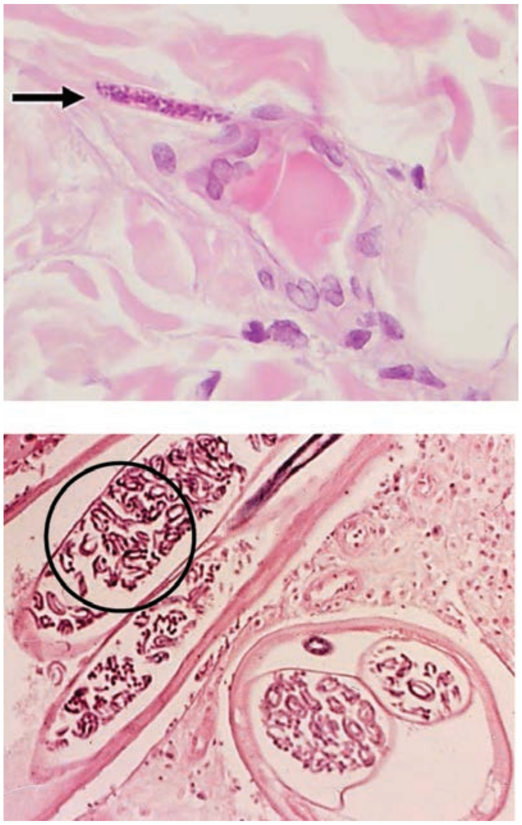

Figure 34.72 *Onchocerca* sp. (Upper) Microfilaria of *Onchocerca* sp. (arrow) detected in biopsied skin in the interstitium of the dermis; H&E stain. (Lower) The gut is seen as a cross section in the lower portion of the image and longitudinally in the upper portion; note the curvy microfilariae in different lengths, depending on the direction of the cut (circle). (From *A Pictorial Presentation of Parasites*: a cooperative collection prepared and/or edited by H. Zaiman.) doi:10.1128/9781555819002.ch34.f72

The prepatent period in humans is 3 to 15 months. Light infections may produce no symptoms, and worms may be free in the tissue; however, in heavy infections, major disease manifestations include dermatitis, onchocercomas (subcutaneous nodules containing adult worms), lymphadenitis, and blindness. Even though there is an inflammatory reaction that causes the formation of a fibrotic capsule (onchocercoma) around the adult, the main pathology appears to be directed against the microfilariae (Fig. 34.72).

Acute attacks of onchodermatitis have resulted in a purplish skin discoloration on the trunk and upper limbs known as mal morado in Central America. Chronically infected skin loses its elasticity and becomes hypertrophic or thickened. As a result of atrophy and loss of skin elasticity, patients may develop premature exaggerated wrinkling of the skin. Skin may become hypo- or hyperpigmented. In Africa, patients may exhibit localized areas of spotty depigmentation surrounded by slightly hyperpigmented zones, occurring mainly on the shins; this condition is known as leopard skin.

A major complication of onchocerciasis has been ocular lesions leading to bilateral blindness. The prevalence of blindness depends on the organism strain and the prevalence of disease within an area, while the degree of eye involvement depends on the duration and severity of infection. Visual problems can include fluffy corneal opacities, sclerosing keratitis, and iridocyclitis leading to glaucoma and cataracts; chorioretinitis and optic atrophy also occur. Eye damage is caused by living and dead microfilariae in the cornea, anterior and posterior chambers, iris, retrolental space, vitreous, choroid, retina, sclera, and optic nerve. Progressive pathology generally develops over time, with resulting blindness seen in adults.

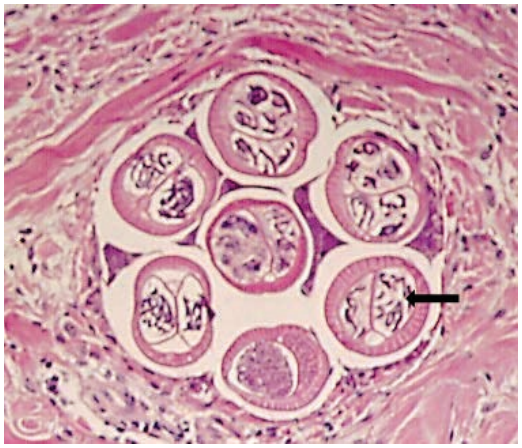

Figure 34.73 *Mansonella streptocerca* in a section of skin. Note the long, slender microfilariae *in utero* (arrow). (From *A Pictorial Presentation of Parasites*: a cooperative collection prepared and/or edited by H. Zaiman.) doi:10.1128/9781555819002.ch34.f73

Mansonella streptocerca

Until recently, *Mansonella streptocerca* was named *Dipetalonema streptocerca*. Adult female and male worms live in the dermal tissues, and the microfilariae are found in the skin, where they can be ingested by *Culicoides* spp. (midges), the insect vectors. Pruritic dermatitis with hypopigmented macules on the skin and lymphadenopathy have been common complaints.

Microfilariae can be found primarily in the upper third of the dermis in the dermal collagen (Fig. 34.73). Changes in the skin include sclerosis of dermal papillae, edema, incontinence of melanin, fibrosis, and cellular infiltrates around blood vessels, and the lymphatics are frequently dilated. In untreated patients, adult worms are occasionally found in the dermis; they do not tend to cause an immune response when alive.

Appendix 34.1 Histologic identification of parasites[a]

Body site	Organisms	Stain	Comments
Intestine	Protozoa		
	Entamoeba histolytica (cecum, ascending colon, sigmoid rectal region; other sites less common); trophozoites and cysts are normally passed in stool	H&E, PAS, trichrome or iron hematoxylin in stool	Differential between organism and histiocyte: in an organism, the nucleus may not be visible; in histiocytes, a portion of the nucleus is almost always visible; both trophozoites and histiocytes stain red with PAS (review nuclear details); histolysis of invaded tissue; flask-shaped ulcers; organisms seen in healthy ulcer margins, not in central, necrotic areas
	Giardia lamblia (duodenum); trophozoites and cysts are normally passed in stool; organisms can be seen in duodenal aspirates or by using other sampling methods (Entero-Test)	H&E, Giemsa, trichrome or iron hematoxylin in stool	Normal to mild to severe blunting of villi; loss of the brush border; infiltration of lamina propria with lymphocytes and granulocytes; chronic inflammation; tissue invasion does not occur; trophozoites may appear as sagittal sections of small, crescentic organisms that may adhere to the epithelial surface; front views will reveal the typical teardrop shape
	Balantidium coli; trophozoites and cysts are normally passed in stool; tissue invasion may occur in the colon and appendix	H&E, trichrome or iron hematoxylin in stool (may be difficult to see on permanent stained smears; wet mount is best)	Simple hyperemia to marked ulcerations (large intestine); very large size (trophozoites); presence of cilia, large cytostome, and prominent macronucleus will distinguish these ciliates from other protozoa; due to large size, cut planes may not reveal all internal morphology; early lesion resembles that of *E. histolytica*, but the opening into the mucosa is larger
	Cryptosporidium spp. have been recovered from mouth to anus, more common in small intestine; oocysts (4–6 µm) are passed in stool; disseminated disease can occur, with oocysts being passed in sputum	H&E, modified acid-fast stains for stool (oocysts positive)	Mild to moderate villous atrophy, increased crypt size, mild to moderate mononuclear cell infiltrates of lamina propria; organisms along brush border are small and measure 3–5 µm; other coccidia and the microsporidia develop within the cells and so are not confused with the brush border location of *Cryptosporidium* spp.
	Cyclospora cayetanensis developmental stages have been seen in jejunal enterocytes, usually at the luminal end rather than at the brush border; tends to resemble developmental stages of *Cystoisospora belli*	H&E, modified acid-fast stains for stool (oocysts positive, but staining variable)	Acute and chronic inflammation, disruption of surface epithelium, villous atrophy, and crypt hyperplasia are seen; intraepithelial organisms within parasitophorous vacuoles, primarily in apical areas; electron microscopy reveals enterocyte vacuolization and many intraepithelial reactive cells.
	Cystoisospora belli (more common in small intestine); oocysts are passed in stool; unsporulated oocysts measure 20–33 µm long by 10–19 µm wide and may contain a single sporoblast (usually seen in cases of diarrhea)	H&E, modified acid-fast stains for stool (oocysts positive)	Same as *Cryptosporidium* spp., but development occurs within the epithelial cells; tissue eosinophilia can be seen

(continued)

Appendix 34.1 Histologic identification of parasites[a] *(continued)*

Body site	Organisms	Stain	Comments
	Microsporidia; identification of organisms to the genus and species levels requires electron microscopy, tissue culture, immunofluorescence studies, or PCR; differentiation of spores from bacteria or small yeasts in stool is extremely difficult	H&E, tissue Gram stains, PAS, silver stains; modified trichrome and calcofluor white used for stool or urine	Developing spores seen within enterocytes; sizes of individual spores are ~1–3 μm in humans; *Enterocytozoon bieneusi* and *Encephalitozoon* (*Septata*) *intestinalis* involved, primarily seen in the compromised host; both organisms can disseminate to other organs and spores can be found in liver, lungs, kidneys, CNS, and cornea
	Trypanosoma cruzi (esophagus, colon); trypomastigote may be found in peripheral blood in the early stage of infection	H&E	Disease of ganglion cells of mesenteric plexuses; can cause severe distention and thinning of visceral wall; scarring, chronic inflammation; amastigotes may shrink, nuclei and kinetoplasts may not be visible in tissue sections and may resemble *Histoplasma*; tissues most often involved include brain, cardiac, and smooth muscle cells
	Nematodes		
	Enterobius vermicularis (cecum, appendix, other sites; may also be found in female reproductive tract or peritoneal cavity); eggs and adult worms recovered on Scotch tape preparations or pinworm paddles; stool not recommended	H&E	Characteristic lateral alae on worm cross sections; eggs *in utero* may also be visible; most often seen in appendix with little or no inflammation
	Ascaris lumbricoides (small intestine, bile ducts, liver, peritoneal cavity); fertilized and unfertilized eggs passed in stool; adult worms may also be seen in stool; migrating larvae may be seen in sputum	H&E	Large size, characteristic muscular wall formed by long, irregular muscle fibers; sectioned (eggs may be seen with their thick, bumpy shells); the body wall has a thick, multilayered cuticle, fibrous-appearing hypodermis (expands to form large lateral chords, within which are seen excretory canals); short, muscular esophagus and simple intestinal tube with an irregular lumen; larval forms may be more difficult to identify
	Strongyloides stercoralis (usually duodenum and upper jejunum; may be in any tissue in disseminated disease); rhabditiform (noninfectious) larvae usually seen in stool; filariform (infectious) larvae, as well as adult worms and eggs, may be seen in stool in hyperinfection cases	H&E	Sections may reveal adult females, well-segmented eggs, and numerous larvae; although the morphology of the adult female may be difficult to see in tissues, the small size of the worm and the presence of developing eggs and larvae close to the adult worm strongly suggest this diagnosis; with hyperinfection, the bowel lining becomes congested and edematous, with possible ulcerations; chronic infection may reveal bowel wall fibrosis
	Hookworms (*Necator*, *Ancylostoma*) (usually upper part of small intestine); hookworm eggs normally passed in stool; eggs of both genera look the same	H&E	Relatively thick cuticle and thin hypodermis; lateral hypodermal chords are usually visible; wide-open mouth sucking the mucosa; adult *Necator* has cutting plates, while *Ancylostoma* has teeth

	Trichuris trichiura (large intestine); whipworm eggs normally passed in stool	H&E	Most sections reveal both the thicker body area ("whip handle"), which lies free in the lumen, and the slender anterior area ("whip"), which is firmly embedded into the mucosa; sectioned eggs may be visible
	Trichinella spp. (duodenum, small intestine)	H&E	Edema, chronic inflammation, hyperemia, serosa petechiae, dilatation of bowel loops; prominent Peyer's patches; swollen intestinal villi, mucin secretion; diffuse infiltration of eosinophils (lamina propria); larvae may be seen and may resemble microfilariae
	Cestodes		
	Taenia saginata (most common), *T. solium*, *Diphyllobothrium latum*; proglottids and/or eggs are normally passed in the stool	H&E	May see loose proglottids and/or eggs in appendix
	Hymenolepis nana; eggs are normally passed in the stool	H&E	Both larval and adult forms may be in intestinal sections in the human
	Echinococcus granulosus (mesentery)	H&E, acid fast	External laminated, anuclear cyst wall; hooklets are acid fast
	Trematodes		
	Schistosoma mansoni, *S. japonicum*, *S. haematobium*, less common schistosomes (*S. mekongi*, *S. intercalatum*); eggs may be seen in urine and/or stool	H&E	Adults and eggs may be seen in the mesentery or mesenteric veins; egg identification may depend on demonstration of spine in section; important to determine if egg contains miracidium larva (indicates active infection); in the wall of the intestinal tract, polyp formation may occur (more eggs found in polyps)
Liver	Protozoa		
	Leishmania donovani	H&E, PAS	Organisms are dot-like in routine section; they are larger (2–4 μm) in tissue impression smear; kinetoplast next to nucleus is very characteristic and differentiates these organisms from *Toxoplasma* (no kinetoplast); *Histoplasma* is PAS positive, while *L. donovani* is PAS negative
	Toxoplasma gondii	H&E, PAS	Resting forms (bradyzoites) are pyriform with no kinetoplast (if many organisms are seen per cyst, they may appear as dots); bradyzoites within cysts are PAS positive; tissue cysts have a very thin wall; tissue cysts of *Toxoplasma* must be differentiated from *Sarcocystis* (seen most frequently in skeletal or cardiac muscle and larger than *Toxoplasma*); when reviewing animal tissues (from dogs), *Neospora caninum* may be present and will mimic *Toxoplasma*

(continued)

Appendix 34.1 Histologic identification of parasites[a] *(continued)*

Body site	Organisms	Stain	Comments
	Microsporidia	See intestine	See information on intestine
	Plasmodium falciparum, *P. vivax*, *P. malariae*, *P. ovale*, *P. knowlesi*	H&E	Exoerythrocytic stages (mature tissue schizonts) measure 45–80 µm and contain 15,000–40,000 merozoites per cell; malarial pigment may be seen in Kupffer cells; capillaries may be filled with parasitized RBCs (pigment is also visible here); the host does not respond to the presence of these organisms; pigment within blood vessels can be seen with routine tissue stains, but the use of polarized light may also be helpful in demonstrating the birefringent granules of malarial pigment
	Nematodes		
	Capillaria hepatica; eggs in human stool would be from the ingestion of parasitized livers, probably from squirrels or other animals (spurious infections—eggs disappear from the feces in a few days)	H&E, trichrome (Masson)	Liver parenchyma; eggs remain in liver and the life cycle does not continue in humans; eggs resemble those of *T. trichiura*, but the shell appears beaded or pitted; polar plugs are less pronounced than in *T. trichiura*; intense granulomatous reaction around eggs; the general egg shape, the bipolar plugs, and striations in the thick shell make this identification relatively easy
	Toxocara cati or *T. canis*, *Baylisascaris* spp. (visceral larva migrans); adult worms play no role in human disease (very rare exceptions)	H&E	Liver contains largest number of larvae; any organ can be affected; eosinophilic granuloma; focal necrosis may occur; larval morphology includes single lateral ala, nonpatent intestine, and large paired excretory columns; *Baylisascaris* larvae are larger than *Toxocara* larvae and have a patent gut and a predilection for the CNS
	Cestodes		
	Echinococcus granulosus; adult worms and/or eggs found only in the small intestine of canids (primarily dogs)	H&E, acid fast, GMS, PAS	External laminated, anuclear cyst wall; thin nucleated inner layer; hooklets are acid fast; calcified cysts often reveal no hooklets; mature cysts contain brood capsules and protoscolices; degeneration of brood capsules results in "hydatid sand" (degenerating protoscolices and hooklets in the cyst fluid); some cysts are sterile
	Echinococcus multilocularis; adult worms and/or eggs found only in the small intestine of canids (primarily dogs and foxes)	H&E, acid fast, GMS, PAS	Alveolar structure with no limiting membrane; scolices seldom present, thus no protoscolices, hooklets, or calcareous corpuscles; laminated and germinal layers are collapsed, folded, and scattered throughout the liver
	Trematodes		
	Schistosoma mansoni, *S. japonicum*, *S. haematobium*, less common schistosomes (*S. mekongi*, *S. intercalatum*); eggs normally passed in urine and/or stool	H&E, trichrome (Masson)	Granulomatous tissue reaction around eggs (lymphocytes, plasma cells, eosinophils); trichrome demonstrates fibrotic tissue; eggs of *S. japonicum* more numerous in liver (greater egg-laying capacity); adult worms seen most frequently in cross or transverse sections within blood vessels in the wall of the intestine or in liver; often the female is seen *in copula*, surrounded by the larger male body

	Fasciola hepatica (bile duct); eggs normally passed in stool	H&E	Large size plus cross section of worm containing intestinal diverticula; eggs may also be seen but are usually collapsed or distorted
	Clonorchis (*Opisthorchis*) *sinensis* (bile duct); eggs normally passed in stool	H&E	May be eosinophilic infiltration and slight thickening of the duct wall; may progress to fibrosis, cirrhosis of liver, biliary obstruction, etc.; long, coiled uterus full of eggs may be seen; adult trematodes in bile ducts may suggest *C. sinensis*, *Opisthorchis* spp., *Dicrocoelium dendriticum*, and *Fasciola* spp.
Spleen	Protozoa		
	Leishmania donovani	H&E, PAS	See information on liver
	Plasmodium falciparum, *P. vivax*, *P. malariae*, *P. ovale*, *P. knowlesi*	H&E	See information on liver
Gallbladder	This organ is seldom invaded by parasites; occasionally, *Cryptosporidium*, microsporidia, *Clonorchis* (*Opisthorchis*) *sinensis*, *Ascaris lumbricoides*, and *Fasciola hepatica* are found; schistosome eggs may also be found		Eggs and/or sections of adult trematodes may be seen; developmental stages of *Cryptosporidium* possible
Kidney	Protozoa		
	Microsporidia	See intestine	See information on intestine
Urinary bladder	Trematode		
	Schistosoma haematobium	H&E, acid fast	Seen within blood vessels, often near the bladder; early inflammation may progress to thickening, hyperplasia, fibrosis, and ulceration; carcinoma may be a complication; terminal egg spine may be visible; important to determine if egg contains miracidium; eggs may be distorted and collapsed; calcified eggs may also be seen; eggs are not acid fast, like those of *S. mansoni* and *S. japonicum*; adult worms may be seen *in copula* within the blood vessels
Lungs	Protozoa		
	Entamoeba histolytica	H&E	Usually extension of liver abscess in the right lower lobe; may occur elsewhere; nucleus is not always visible; should be area of histolysis around organisms
	Toxoplasma gondii	H&E	Cysts look like those in the liver; tachyzoites are crescent shaped, especially when released from the cells
	Cryptosporidium spp.	H&E	Organism morphology similar to that in intestine; organisms may be seen in sputum in disseminated disease

(continued)

Appendix 34.1 Histologic identification of parasites^{a} *(continued)*

Body site	Organisms	Stain	Comments
	Microsporidia	Tissue Gram stains, PAS, silver stains, H&E	Organism morphology similar to that in intestine; spores may be found in sputum
	Nematodes		
	Strongyloides stercoralis, *Ascaris lumbricoides*, hookworm, *Toxocara* spp., *Wuchereria bancrofti*, *Brugia malayi*, *Dirofilaria immitis*	H&E	Migrating larvae (*Strongyloides*, *Ascaris*, hookworm, *Toxocara* spp.) may be seen; microfilariae (*Wuchereria*) may cause an eosinophilic granuloma (pneumonitis, alveolar hemorrhage, edema)
	Trematodes		
	Paragonimus westermani, other *Paragonimus* spp.; eggs can be found in sputum and/or stool	H&E	Reaction by lung tissue isolates the worm in a thick, fibrous capsule containing hemorrhagic, purulent exudate and eggs; adults typically paired, surrounded by fibrous capsule; spines on tegument and typical eggs make the diagnosis relatively easy
Heart	Protozoa		
	Entamoeba histolytica	H&E, PAS	May be present; pericardial tamponade may occur
	Trypanosoma cruzi	H&E	Amastigotes are morphologically identical to those of *L. donovani* found in the macrophages of the reticuloendothelial system; inflammatory cell infiltrates, interstitial edema, and separation of myofibers
	Toxoplasma gondii	H&E	Cysts appear like those in liver (no kinetoplast as in amastigotes of *T. cruzi*)
	Microsporidia	See intestine	See information on intestine
	Plasmodium falciparum (most important), *P. vivax*, *P. malariae*, *P. ovale*, *P. knowlesi*	H&E	May be marked congestion of the capillaries; blocked with parasitized RBCs and malarial pigment; evidence of anoxia (cloudy swelling, fatty degeneration, myocardial infarcts) may be seen
Skeletal muscle	Protozoa		
	Sarcocystis spp. (rare)	H&E, GMS	Cylindrical cysts (Miescher's tubes) formed (double outer membrane and transverse trabeculae separating the cyst into closed compartments packed with spores); silver stain will clearly reveal the external capsule and septa
	Microsporidia	PAS, AFB, GMS, H&E	Organisms in the genera *Pleistophora*, *Trachipleistophora*, and *Anncaliia* can be found in muscle in compromised hosts (cases on record rare); atrophic and degenerating muscle fibers full of spores (*Pleistophora* in clusters of ~12 organisms); each cluster enclosed by enveloping membrane (pansporoblastic membrane); spores measure 2.8 by 3.4 µm

	Nematode		
	Trichinella spp.	H&E	Diaphragm most commonly invaded; biopsy usually not performed until after day 17, when larvae present a typical, coiled appearance; old, calcified cysts may be difficult to recognize
	Cestode		
	Taenia solium (cysticercosis)	H&E	May also occur in brain, eye, muscles, heart, liver, lungs, abdominal cavity; cyst is oval or round and contains one invaginated scolex with crown of hooklets and four suckers; larva is usually surrounded by tissue reaction capsule, which is wrinkled after tissue processing (very typical appearance, often diagnostic even without cross section of scolex); cysticercus has a dark-staining spiral canal and a scolex surrounded by a thin, lightly staining bladder wall; parenchymatous portion consists of the invaginated scolex with its spiral canal, four suckers, and an armed rostellum with hooks; surface of spiral canal is deeply folded; parenchyma is usually filled with calcareous corpuscles; racemose form of cysticercosis appears as multiple sections of bladder wall tegument (scolex and spiral canal not seen)
Skin and subcutaneous tissue	Protozoa		
	Leishmania spp.	H&E, GMS	See information on liver
	Nematodes *Wuchereria bancrofti*, *Brugia malayi*	H&E	Adults in lymphatic vessels (may be diagnosed in tissue sections); microfilariae in blood
	Loa loa		Adults in subcutaneous tissue; microfilariae in blood
	Onchocerca volvulus		Adults in subcutaneous nodules or in loose connective tissues from deeper areas within the body; may be diagnosed in tissue sections (fibrous nodules); microfilariae in skin; accidental infections with animal species of *Onchocerca* may occur; key features of thick cuticle, transverse ridges, and striations in the middle layer of cuticle are helpful
	Mansonella ozzardi, *M. perstans*, *M. streptocerca*, *Dirofilaria* spp.		Adults in body cavities (abdominal, pleural) and pericardium; microfilariae in blood (*M. streptocerca* in skin)
	Hookworm larvae	H&E	Differentiate from *Strongyloides* spp. (not found in skin)

(continued)

Appendix 34.1 Histologic identification of parasites[a] *(continued)*

Body site	Organisms	Stain	Comments
	Cestodes		
	Spirometra spp. (sparganosis)	H&E	Larvae often invade subcutaneous tissues or muscles (in or about the eyes); acute inflammatory reaction, which is more severe as larva dies and is absorbed; solid-bodied sparganum lacks suckers and surrounding bladder wall seen in other cysticerci
	Sparganum proliferum	H&E	Produces a more severe reaction with metastatic branching and spread throughout the tissues; no scolex seen
	Arthropods		
	Demodex folliculorum (mite)	H&E	Invades hair follicles and sebaceous glands; may be chronic inflammatory cells around mites
	Sarcoptes scabiei (itch mite)	H&E	Superficial skin layer (never below epidermis); preferred site is interdigital spaces, may be elsewhere (heavy infestations, i.e., Norwegian scabies)
	Tunga penetrans (chigoe, sand flea)	H&E	Prefers toes; causes intense itching, even pain
Lymphatic vessels	Nematodes		
	Wuchereria bancrofti, *Brugia malayi*	H&E	Damage ranges from inflammatory sensitization to elephantiasis (tissue hyperplasia)
Testes	Nematode		
	Wuchereria bancrofti	H&E	Worms may be calcified and lymphatic vessel replaced by collagen tissue
Nervous system	Protozoa		
	Naegleria fowleri, *Acanthamoeba* spp., *Balamuthia mandrillaris* (leptomyxid ameba), *Sappinia diploidea*	H&E	Brain lesions demonstrate congestion or hemorrhages, marked cellular infiltration (mononuclear, polymorphonuclear), and abscess formation; trophozoites have large karyosome and no chromatin on nuclear membrane; may be difficult to differentiate *Acanthamoeba* from *Balamuthia*
	Entamoeba histolytica	H&E, PAS	Histolysis of invaded tissue; trophozoite nucleus may not always be visible
	Microsporidia, *Encephalitozoon* spp., *Vittaforma* spp., *Nosema* spp., *Anncaliia* spp., *Trachipleistophora* spp., *Microsporidium* spp.	PAS, AFB, GMS	Spores range from 2 to 4 μm and have been found in cerebrospinal fluid; appearance in tissue similar to other body sites; eye infections reported with *Encephalitozoon*, *Vittaforma*, *Nosema*, and *Microsporidium*

Trypanosoma brucei gambiense, *T. b. rhodesiense*	H&E	May be no reactive changes around organisms (brain); undulating membrane may be difficult to see
Toxoplasma gondii	H&E	See information on liver; there is no cyst formation in an early acute infection (central nervous system more commonly involved)
Plasmodium falciparum	H&E	Congested blood vessels containing parasitized RBCs and malarial pigment
Nematodes		
Angiostrongylus cantonensis	H&E	Produces eosinophilic meningoencephalitis; cross section of worm is characterized by high muscle fibers under the cuticle with two prominent chords; cellular infiltrates composed of eosinophils and mononuclear cells
Toxocara spp.	H&E	Granulomas or necrotic areas within periretinal inflammatory membrane
Cestodes		
Taenia solium (cysticercosis)	H&E	May induce fibrous encapsulation; pronounced cellular reaction may occur as larva begins to die
Echinococcus granulosus	H&E	Wall is finely laminated and has affinity for either acidic or basic dyes
Trematodes		
Schistosoma japonicum	H&E	Hyperemia of meninges overlying granulomas in brain
Paragonimus spp. (any area of brain)	H&E	Cysts may contain eggs, cellular debris, Charcot-Leyden crystals, eosinophils, plasma cells, and lymphocytes; granulomas form around eggs

---

[a] Data from references 1–6; not every body site or every parasite is included in this table. AFB, acid-fast bacillus; CNS, central nervous system; GMS, Gomori methenamine-silver stain; H&E, hematoxylin and eosin stain; PAS, periodic acid-Schiff stain; RBC, red blood cell.

Appendix 34.2 General characteristics of helminths

Characteristic	Nematodes	Cestodes	Trematodes	Acanthocephala	Pentastomes (tongue worms)
General	Elongate-cylindrical, bilaterally symmetrical with secondary triradiate symmetry at anterior end; integument nonnucleated cuticula secreted by hypodermis (may be smooth, striated, bossed, or spined); body has 3 main layers (cuticle, hypodermis, somatic muscles); 4 chords arise from hypodermis and project into body cavity; no circular muscles; body cavity is pseudocele (not lined with mesothelium); all viscera suspended in pseudocele; all separate sexes	Adult tapeworm consists of few to many egg-producing units (proglottids) which develop from distal end of scolex; chain called strobila; each proglottid contains male and female genital organs (hermaphroditic); food absorbed through integument; at surface is layer of microvilli (microtriches) over entire outer surface (comparable to brush border of host intestinal epithelium); primitive excretory system; tegument homogeneous and noncellular; circular, longitudinal muscles; proglottids filled with mesenchyme or parenchyma (loose meshwork of branched cells and fluid-filled spaces); calcareous corpuscles usually present in parenchyma	Flukes usually dorsoventrally flattened and hermaphroditic (other than schistosomes); have oral and ventral suckers; integument frequently covered by spines; mesenchyme below integument; circular, oblique, longitudinal muscles; alimentary canal is inverted Y shape; nutrients generally absorbed through tegument	Canals in tegument and arrangement of deeper layers of body wall distinctive; proboscis (retractile into proboscis sheath) armed with spines and body proper; separate sexes; probably related to tapeworms	Body elongate, tongue-like, cylindrical, or moniliform, with many pseudosegments but no separation into head, thorax, and abdomen; head with median subterminal mouth and two pairs of hollow, retractile claws; eyes lacking; sexes separate; striated muscles; have been considered highly modified annelids
Body cavity	Pseudocoelom—yes	No—parenchyma, containing calcareous corpuscles (unique to cestodes, prominent in larval forms)	No—filled with mesenchyme	Pseudocoelom—no; loose parenchymous matrix	Reduced—yes
Body tegument (wall)	Cuticle, hypodermis; cuticle has striations, annulations, or ridges; hypodermis has dorsal, ventral, and lateral chords; well-developed, longitudinally oriented, smooth muscles	Smooth	Smooth or spinous, two suckers (oral and ventral/acetabulum); syncytial epithelium bounded externally by a plasma membrane and internally by trilaminated plasma membrane	Thick, multilayer; outer plasma membrane, thin fibrous layer, thick feltlike middle layer, very thick fibrous inner layer; structure of proboscis with hooks and spines on body surface key features; canals present in tegument	May have spines; cuticle may have prominent spines or may be smooth; subcuticular glands lie below cuticle, as do striated muscle fibers; cuticle contains chitin and has sclerotized openings that are diagnostic for pentastomids

Cuticle (nematodes)	3 layers (cortical, median, basal); surface may have longitudinal ridges (may be called alae); may also have inflations called bosses or plaques	Surface may be covered with hairy projections called microtriches	True cuticle and epidermis shed or fails to develop	NA[a]	NA
Hypodermis (nematodes)	Layer of cells lying between the cuticle and muscles; projects into the pseudocoelom at the dorsal, ventral, and lateral positions to form 4 chords; secretes the cuticle	NA	NA	NA	NA
Chords	Lateral chords most conspicuous; in some groups, lateral secretory/excretory columns lie within or associated with lateral chords	NA	NA	NA	NA
Muscle fibers	Longitudinally oriented, smooth muscles; no circular muscles	Longitudinal and circular smooth muscles	Longitudinal, circular, and diagonal smooth muscles	Longitudinal and circular smooth muscles	Striated muscle fibers
Body muscles	Somatic and specialized				
Somatic (nematodes)	Elongate, spindle-shaped cells; lie in rows under hypodermis, are parallel to and overlap each other; each cell has basal, contractile portion and cytoplasmic, noncontractile portion	Between tegument and subtegumental nuclei are 2 thin layers of muscle fibers; outer layer is circular fibers and inner layer is longitudinal; some differences among species	Outer layer of circular muscle, inner layer of longitudinal muscle; dorsoventral muscle fibers course throughout the parenchyma and surround internal organs	Outer circular and inner longitudinal fibers	Acidophilic glands can be seen in larval sections

(continued)

Appendix 34.2 General characteristics of helminths *(continued)*

Characteristic	Nematodes	Cestodes	Trematodes	Acanthocephala	Pentastomes (tongue worms)
Specialized (nematodes)	Associated with digestive and reproductive systems				
Body cavity contents	Contains digestive tube and tubular gonads	No	No	No digestive system	Yes, intestine large
Digestive system	Mouth, buccal cavity, esophagus, intestine, rectum	No	Oral opening, pharynx, esophagus which bifurcates into a pair of blindly ending tubular intestinal ceca	No—lacunar system; nutrients absorbed through body wall	Simple gut
Reproductive system	Separate sexes; simple tubular structures; usually 1 testis and paired ovaries	Hermaphroditic	Hermaphroditic; 2 testes and 1 ovary; exception is seen with schistosomes (separate sexes)	Separate sexes; 2 testes and 1 ovary, breaks up into "floating" ovaries	Separate sexes
Nervous system	Not relevant for identification	Not relevant for identification	Not relevant for identification	Not relevant for identification	Not relevant for identification
Excretory system	Referred to as secretory/excretory system; varies from large gland cell that opens to the exterior via a duct in ventral midline to being free in the pseudocoelom	Not relevant for identification	Bilaterally symmetrical	NA	NA

[a] NA, not applicable.

Appendix 34.3 Staining characteristics

Characteristic	Comments
Staining action	**Substantive:** Stain that acts immediately and directly on the tissue without the intervention of any other substance **Adjective:** Tissue is first treated with an agent, which in turn attaches the stain to the tissue (mordant staining) **Impregnation:** Involves the deposition of sensitive metallic substances over selected cells and tissue structures that are rendered visible by subsequent reduction of the metal
Staining time	**Progressive:** Using the microscope, performed by watching the degree of staining at various points during the process and stopping the process when the desired staining action has been achieved **Regressive:** Used for the best sharpness of differentiation; whole tissue is stained and then differentiated to remove excess dye from the parts that should be relatively unstained
Action on tissue	**General:** Stain that colors all parts of the tissue equally, providing no significant differentiation **Selective:** Stain that differentiates between classes of tissue or between parts of cells
Differentiation	Using regressive staining methods, the process of removing excess stain is called differentiation; this usually provides sharp staining contrasts because the hydronium and hydroxide ions in the solvents used for differentiation diffuse more rapidly than any dye ion; some of the ways in which a tissue section may be differentiated include the use of acidic or basic medium and excess mordant, buffers, or oxidizers
Staining mechanisms	**Capillarity and osmosis:** Account for penetration of the dye into the interior of the tissue **Absorption or solution:** Passage of the dye molecule from the dye bath solution to the solution in the substance being dyed **Adsorption:** Deposition of dye on the surface of the dyed material (physical surface adsorption plus salt linkages of dye to the protein chain)
Chemical factors	**Acid-base:** Based on the fact that certain cell parts are assumed to be acidic and other parts are alkaline **Ionic strength of dye solution:** Dissolved salt, either neutral or buffered, in the dye solution influences the interaction of dye and tissue; increased ionic strength decreases the staining of both acidic and basic dyes; salt ions may compete with color ion for binding site on the protein molecules **Dye concentration:** Greater amounts of dye are bound with increasing concentrations of the dye; amount of dye bound by tissue is limited by the number of available binding sites **Fixation of tissue:** When cells are fixed, the affinity for stains increases; protein molecules are reorganized so that chemical groups are more available to the dye (characteristic shared by all fixatives); greater basic dye uptake after formalin fixation; more acidic dye uptake after fixation with mercuric chloride fixatives **Temperature:** Increase in temperature increases the diffusion rate of dye molecules; increase also causes protein molecules to swell the fibers, rendering them more open to dye penetration **Staining equilibrium:** Staining is a reversible reaction; when the solution environment is changed, the equilibrium concentration in the tissue is altered

Appendix 34.4 Nuclear and cytoplasmic stains

Stain	Comments
Nuclear stains	
Technical classification	**Reagents used:** Dyes can be either natural or synthetic; natural dyes include cochineal, carmine, and hematoxylin; synthetic dyes include derivatives of substances found in coal tar, oxazines (safranin, basic fuchsin), thiazins (methylene blue, toluidine blue), crystal violets, and gentian violets **How reagents are used:** Depending on mordants, other solutions, etc., results will vary
Nucleic acids	**DNA (nucleus):** Feulgen reaction used to demonstrate DNA (periodic acid-Schiff stain) **RNA (nucleolus, cytoplasm/mitochondria, ribosomes):** Methyl green-pyronin used to demonstrate DNA (methyl green) and RNA (pyronin)
Cytoplasmic stains	
Definition	Usually consist of acidic dyes that contain sulfonic and carboxylic acids that combine with tissue bases, especially those proteins with an excess of the basic amino acids such as arginine, lysine, hydroxylysine, and histidine
Common cytoplasmic stains	**Picric acid:** Nitro dye used as a yellow contrast stain in collagen methods, as well as with hematoxylin **Eosin:** Used as a counterstain with hematoxylin; can be used as an aqueous or alcoholic solution
Mordant	
Definition	A substance capable of combining with a dye and the material to be dyed, thereby increasing the affinity or binding of the dye

Appendix 34.5 Carbohydrate stains

Carbohydrates	Stains[a]	Comments
Polysaccharides	**Iodine:** Starch and by-products (amylose and amylopectin) give blue color; glycogen and amyloid give a red-brown reaction **PAS:** glycogen strongly positive	Glycogen is the only polysaccharide that occurs in higher animals (liver cells, muscle, cartilage, certain parathyroid cells); starch occurs as carbohydrate reserves in plants; cellulose occurs in cell walls of plants
Mucopolysaccharides (acidic mucopolysaccharides, neutral mucopolysaccharides [not very relevant])	**Iodine:** Starch and by-products (amylose and amylopectin) give blue color; glycogen and amyloid give a red-brown reaction **PAS:** For carbohydrates, glycogen is strongly positive, acid mucopolysaccharide does not stain, neutral mucopolysaccharide is not present in significant amounts, but chitin will stain; for lipids, glycolipids and phospholipids are PAS positive; for proteins, pale background color probably due to very small amounts of carbohydrate	Hyaluronic acid is the only example of a simple acidic mucopolysaccharide; main component of ground substance (substance that embeds collagen and elastic fibers) (eye, synovia, some pathologic conditions); for sulfated acidic mucopolysaccharides, heparin is found in a large variety of tissues (tissue mast cells are the site of production), and chondroitin sulfate is found in connective tissue and cartilage
Mucoproteins	**PAS:** Positive **Toluidine blue for mucin:** Positive	Complexes in which the protein, rather than the carbohydrate, is the principal constituent; found in blood group antigens, digestive and respiratory, etc.; the term "mucin" usually signifies mucoprotein
Glycoproteins	**PAS:** Positive	Similar to mucoproteins (hexosamine content, <4%); collagen, reticulin fibers; frequently synonymous with "mucoids"
Glycolipids	**PAS:** Positive	Contain 1 mol each of a fatty acid, sphingosine, and hexose; examples are cerebrosides and gangliosides

[a] PAS, periodic acid-Schiff.

Appendix 34.6 Most likely, secondary, and rare body site locations for human protozoan parasites[a]

Parasite	Life cycle stage	Most likely site(s)	Secondary site(s)	Rare site(s)
Amebae				
Entamoeba histolytica	T	Colon	Liver, lungs, kidneys, skin, small intestine	Brain, heart, lymph nodes, peritoneal cavity, reproductive system, eye, spleen, bone
Entamoeba gingivalis[b]	T	Buccal cavity		
Acanthamoeba spp.	T/C	Eye, brain, skin		Lungs, bone
Balamuthia mandrillaris	T/C	Brain		
Naegleria fowleri	T	Brain		
Sappinia diploidea	T	Brain		
Flagellates				
Giardia lamblia	T	Small intestine, appendix		
Leishmania spp.	A	Skin, liver, spleen, bone marrow		Reproductive system, eye
Trypanosoma cruzi	A	Heart, bloodstream, bone marrow	Muscle, brain, colon, female reproductive system	Stomach, small intestine, lymph nodes
Ciliate				
Balantidium coli	T	Small intestine, appendix, colon		Lymph nodes, peritoneal cavity
Apicomplexans				
Cryptosporidium spp.	CO, O	Small intestine, appendix	Stomach, lungs, liver, gallbladder	
Cyclospora cayetanensis	CO, O	Small intestine		
Cystoisospora belli	CO, O	Small intestine		Lungs, lymph nodes
Sarcocystis spp.	CO	Muscle, heart, small intestine, blood vessel walls		
Toxoplasma gondii	B, Ta	Brain, lungs, heart, lymph nodes, eye, female reproductive system, spleen	Skin, liver, gallbladder, kidneys, pancreas, small intestine, male reproductive system, bone	Bladder, ureters
Plasmodium spp.	M	Bloodstream, red blood cells	Liver	
Microsporidia				
Enterocytozoon bieneusi	S	Small intestine, colon	Lungs, liver, kidneys	
Encephalitozoon intestinalis	S	Small intestine, colon	Lungs, heart, liver, gallbladder, kidneys	
Encephalitozoon spp.	S	Small intestine, colon, eye	Lungs, heart, liver, gallbladder, kidneys, bloodstream vessels, lymph nodes	
Pleistophora	S	Muscle	Eye	
Trachipleistophora	S	Muscle	Eye	
Anncaliia	S	Eye	Vocal cord	
Nosema	S	Eye, muscle (*Nosema*-like)		
Vittaforma corneae	S	Eye		
Microsporidium	S	Eye		
Tubulinosema acridophagus	S	Liver, BAL	Skin	Retina

[b] If found in sputum, can be misdiagnosed as *E. histolytica* from pulmonary abscess.

Appendix 34.7 Most likely, secondary, and rare body site locations for human helminth parasites[a]

Parasite	Life cycle stage	Most likely site(s)	Secondary site(s)	Rare site(s)	Comments
Intestinal nematodes					
Ascaris lumbricoides	A/L	Small intestine (A), lungs (L)	Liver, gallbladder, kidney, pancreas (A)	Pleural cavity	Tendency to migrate if disturbed
Enterobius vermicularis	A	Small intestine, colon	Peritoneal cavity, female reproductive system	Lungs	Extremely common; eggs highly infectious
Trichuris trichiura	A	Colon	Small intestine		"Whipworm"
Capillaria philippinensis	A	Small intestine			Eggs resemble *Trichuris*
Hookworms (*Ancylostoma duodenale*, *Necator americanus*)	A/L	Small intestine (A), lungs (L)			Eggs identical
Trichostrongylus spp.	A	Small intestine			Similar to hookworm disease
Strongyloides stercoralis	A/L	Small intestine (A), small intestine (L)	Lungs, colon (L)	Liver, kidneys (L)	May cause disseminated disease
Tissue nematodes					
Trichinella spp.	A/L	Small intestine (A), muscle (L)		Brain (L)	Pork, bear, walrus meat
Baylisascaris procyonis	L	Brain	Muscle, lungs, heart, liver, gallbladder		Associated with raccoons
Lagochilascaris spp.	A/L	Skin, buccal cavity		Lungs	Rare human infection
Toxocara canis	L	Eye, liver	Lungs	Brain, heart	Causes VLM and OLM
Toxocara cati	L	Eye, liver		Brain, heart	Causes VLM and OLM
Ancylostoma spp.	L	Skin	Muscle	Eye	Causes OLM
Dracunculus medinensis	A	Skin		Pericardium, eye, brain	"Fiery serpent"
Angiostrongylus cantonensis	A	Brain		Lungs, eye	Rat lungworm
Angiostrongylus costaricensis	A	Small intestine, peritoneal cavity			Abdominal disease
Gnathostoma spinigerum	L	Skin, muscle	Brain	Small intestine, eye	Larvae migrate throughout the body
Anisakis spp.	L	Stomach, small intestine		Peritoneal cavity	Associated with sushi and sashimi
Pseudoterranova decipiens	L	Stomach, small intestine		Peritoneal cavity	Associated with sushi and sashimi
Capillaria hepatica	A	Liver			No eggs found in stool
Thelazia spp.	A	Eye			Reported in California
Filarial nematodes					
Wuchereria bancrofti	A	Lymphatics		Lungs, eye	Elephantiasis
Brugia malayi	A	Lymphatics		Lungs	Elephantiasis
Brugia spp. (zoonotic)	A	Lymphatics		Lungs	
Onchocerca volvulus	A	Skin			"River blindness"
Onchocerca spp. (zoonotic)	A	Skin			
Loa loa	A	Skin, eye			African eye worm
Mansonella perstans	A	Peritoneal cavity		Eye

Appendix 34.7 *(continued)*

Parasite	Life cycle stage	Most likely site(s)	Secondary site(s)	Rare site(s)	Comments
Mansonella streptocerca	A	Skin			
Mansonella ozzardi	A	Skin			
Dirofilaria immitis	A	Lungs	Heart	Skin	"Coin" lesions
Dirofilaria repens	A	Skin, eye		Lungs	
Dirofilaria spp.	A	Skin, eye		Bloodstream	
Unusual nematodes					
Oesophagostomum spp.	A/L	Colon	Peritoneal cavity		Nodular mass lesions
Mammomonogamus spp.	A	Lungs, buccal cavity			Y-shaped worms
Dioctophyma renale	A/L	Kidney (A), skin (L)			Primarily right kidney
Tissue cestodes					
Taenia solium (cysticercus)	L	Skin, muscle, brain, eye	Heart		Pork tapeworm
Echinococcus granulosus (unilocular cystic hydatid)	L	Liver, lungs	Muscle, brain, heart, kidneys, eye, spleen, bone	Peritoneal cavity	Sheep-sheepdog cycle; hydatid disease
E. multilocularis (alveolar cystic hydatid)	L	Liver	Brain, lungs	Peritoneal cavity	Difficult to treat
Taenia/Multiceps spp. (coenurus)	L	Skin, muscle, brain, eye	Peritoneal cavity		Most often in central nervous system
Spirometra/ Diphyllobothrium spp. (spargana)	L	Skin, muscle	Lungs, heart, peritoneal cavity, reproductive system, bladder	Brain, eye	Use of raw, infected tissue as poultice
Mesocestoides spp.	L	Peritoneal cavity			Approximately 20 cases
Intestinal trematodes					
Heterophyids	A/E	Small intestine	Heart (E)		Eggs almost identical
Clonorchis/ Opisthorchis	A/E	Liver			Chinese liver fluke
Fasciola	A/E	Liver		Skin, peritoneal cavity	Sheep liver fluke
Paragonimus spp.	A/E	Lungs	Skin, brain (A/E); muscle (A/E)		Lung fluke
Schistosoma mansoni	A/E	Blood vessels, peritoneal cavity, mesenteries (A); colon (E)	Brain (E)	Liver, gallbladder	(E) Inferior mesenteric veins (A)
Schistosoma haematobium	A/E	Bladder, ureters, blood vessels (A); colon (E)			Vesicle, prostate, uterine plexuses (A)
Schistosoma japonicum	A/E	Peritoneal cavity, mesenteries, blood vessels	Lungs (E); brain, small intestine, colon (E)	Liver, gallbladder	(E) Superior mesenteric veins (A)
Unusual trematodes					
Alaria spp.	L	Skin	Stomach, lymph nodes, liver	Eye	Ingestion of poorly cooked frogs (legs)
Arthropods					
Demodex spp.	A/L	Skin (hair follicles)			Follicle mite
Sarcoptes scabiei	A/L	Skin			Itch mite, scabies

Appendix 34.7 Most likely, secondary, and rare body site locations for human helminth parasites[a] *(continued)*

Parasite	Life cycle stage	Most likely site(s)	Secondary site(s)	Rare site(s)	Comments
Tunga penetrans	A	Skin			Chigoe, sand flea
Pentastomes	L	Lungs, liver, peritoneal cavity	Lymph nodes, lymphatics in buccal cavity	Eye	Tongue worms
Myiasis (fly larvae)					
Cochliomyia	L	Nose, ear, brain			Infects living tissue; common name is New World screwworm
Calliphora	L	Skin, intestine, GU tract			Infects dead tissue; common name is bluebottle
Cordylobia	L	Skin, usually feet			Infects subcutaneous boils; common name is Tumbu fly
Sarcophaga	L	GI tract, skin, GU tract, vagina			Infects dead or living tissue, depending on species; common name is flesh fly
Dermatobia	L	Skin, boils, brain			Infects living tissues; common name is human botfly
Cuterebra	L	Skin, eye			Infects living tissue; common name is North American botfly
Gastrophilus	L	Skin, migrates to eye			Undergoes "larva migrans" cutaneous migration; common name is horse botfly
Hypoderma	L	Skin, eye, nasopharynx			Undergoes extensive larval wandering (limbs); common name is warble fly
Oestrus	L	Nasopharynx, eye, sinuses			Infects living tissue, resembles conjunctivitis; common name is sheep nasal botfly

[a] Adapted from references 1, 4, and 5. A, adult (for filarial nematodes, includes immature adults, not microfilariae); E, eggs; GI, gastrointestinal tract; GU, genitourinary tract; L, larva(e).

Medically Important Arthropods

Arthropods and their relationship to disease
Biological vectors of microorganisms
Bites and envenomation
Tissue invasion
Entomophobia and delusional infestation (parasitosis)
Class Insecta (insects)
Order Diptera (flies, mosquitoes, and midges)
Myiasis
Order Hemiptera (true bugs)
Order Coleoptera (beetles)
Order Siphonaptera (fleas)
Order Anoplura (sucking lice)
Order Mallophaga (biting and chewing lice)
Order Hymenoptera (bees, wasps, and ants)
Order Blattaria (cockroaches)
Class Arachnida (ticks, mites, spiders, and scorpions)
Subclass Acari (ticks, mites, and chiggers)
Subclass Araneae (spiders)
Subclass Scorpiones (scorpions)
Other arthropods
Class Chilopoda (centipedes)
Class Diplopoda (millipedes)
Class Crustacea (copepods, crabs, crayfish, etc.)
Control of arthropods of medical importance
Physical control
Biological control
Chemical control

Over 1 million species in the animal kingdom are found in the phylum Arthropoda. These invertebrates are characterized by the possession of an exoskeleton, an internal hemocele that is filled with hemolymph and the internal organs, and a body that is usually divided into the head, thorax, and abdomen. Arthropods develop through a process called metamorphosis, often involving three or four stages: egg, nymph, and adult (bedbugs, sucking lice, and cockroaches); egg, larva, pupa, and adult (flies, fleas, mosquitoes, and bees); or egg, larva, nymph (one or more), and adult (ticks and mites). Classification of the medically important arthropods is shown in Table 35.1 (1–8).

The importance of this group is due primarily to the morbidity and mortality of the various diseases they transmit, as well as their wide geographic distribution. Arthropods can transmit disease via mechanical transmission, in which the arthropod vector is not a part of the life cycle of the organism, and biological transmission, in which the arthropod vector is an integral part of the life cycle of the organism (multiplication or development or both in the vector). Vector-borne parasitic human infections are listed in Table 35.2. In addition to serving as vectors of various infections, certain arthropods may cause some degree of pathologic changes as a result of their bites, stings, or presence on or in the body. Examples are given in Table 35.3 and Appendix 35.1 of this chapter. Specific diagnostic tests and recommended therapy for the more common arthropods are listed in Appendix 35.2. Specific terms related to the identification of specific arthropods can be found in Appendix 35.3. The relative sizes of some of the more important arthropods can be seen in Fig. 35.1.

Arthropods and Their Relationship to Disease

Biological Vectors of Microorganisms

As biological vectors, arthropods can serve as intermediate hosts for human infections or can accidentally carry microorganisms from one host to another. They can transmit various protozoa (the agents of malaria, leishmaniasis, and trypanosomiasis, and *Babesia* spp.), helminths (filarial worms, lung flukes, and tapeworms), bacteria (*Yersinia pestis* and *Francisella tularensis*), rickettsiae (the agents of typhus, trench fever, and bartonellosis), chlamydiae (the agents of trachoma, lymphogranuloma venereum, and psittacosis), spirochetes (the agents of relapsing fever, yaws, and Lyme disease), and viruses (arboviruses).

doi:10.1128/9781555819002.ch35

TABLE 35.1 Classification of medically important arthropods[a]

Class	Order	Common name
Insecta	Diptera (true flies)	Blackflies
		Sand flies
		Mosquitoes
		Biting midges
		Deerflies
		Botflies
		Warble flies
		Houseflies
		Tsetse flies, etc.
		Flesh flies
		Blowflies
		Louseflies
	Hemiptera (true bugs)	Assassin bug
		Bedbugs
	Coleoptera (beetles)	Beetles
	Siphonaptera (fleas)	Fleas
	Anoplura (sucking lice; thrips)	Body/head lice
		Crab louse
	Mallophaga (biting/chewing lice)	Dog louse
	Hymenoptera (bees/wasps/relatives)	Honeybees
		Wasps
		Ants
	Blattaria (cochroaches)	German cockroach
		American cockroach
Arachnida	Acari (S)	Hard ticks
		Soft ticks
		Itch mites
		Chiggers
		Follicle mites
	Araneae (S)	Spiders
	Scorpiones (S)	Scorpions
Pentastomida		Tongue worms
Diplopoda		Millipedes
Chilopoda		Centipedes
Crustacea (SP)	Copepoda (S)	Water fleas
	Decapoda	Crabs, crayfish

[a] S, subclass; SP, subphylum.

As vectors, arthropods may serve as mechanical vectors of the etiologic agent, merely transporting the organisms from one host to another or from the environment to a host. However, most agents of arthropod-borne disease use the arthropod as a biological vector, requiring a period of incubation or development in this host. Although most vectors ingest the etiologic agent of disease, they transfer the organisms to humans in several ways, including via an arthropod-derived vomit drop on food or drink or in a puncture wound. Fecal pellets may also contain the infecting organism, as can the hemolymph if the vector is crushed on the skin. Salivary secretions can also contain the infective organisms.

A number of criteria must be fulfilled before an arthropod can be considered a disease vector. The suspected vector must be known to bite humans in a geographic area where human infections are documented. Second, the geographic distribution of the suspected vector must include the distribution of the disease in humans. Third, the causative agent of disease must be isolated from wild-caught vectors and must be the same species as that causing disease in humans. Fourth, it must be shown that naturally or experimentally infected vectors can maintain the infection throughout the complete life cycle of the parasite. Finally, experimental transmission of the parasite by a bite is generally considered proof of the vector's ability to transmit the organism.

Bites and Envenomation

Most individuals have come in direct contact with arthropods which are problems because of their bites and human sensitivity to their saliva or toxins. Human contact occurs when arthropods are feeding or bite in self-defense. Generally these bites do not cause serious problems, unlike stings, for which the reaction may be more severe. The outcome depends on a number of factors, including the arthropod involved, the amount of toxic substance introduced into the body, the physical condition of the bite victim, and possible previous exposure. Individual responses can vary from mild itching and redness to life-threatening reactions.

Envenomation is usually associated with stings; however, some groups can introduce venom during a bite. These include some of the spiders, particularly the widow spiders, violin spiders, and some tarantulas. Arthropods usually associated with the introduction of saliva during the act of biting include the Acari (ticks and mites), Anoplura (sucking lice), Araneae (spiders), Chilopoda (centipedes), Diptera (flies, mosquitoes, and biting midges), Hemiptera (true bugs: bedbugs, kissing bugs, and triatomid bugs), and Siphonaptera (fleas).

Human contact with some groups of urticating caterpillars (which have body hairs that can inject venom) may also produce mild to serious skin conditions (Fig. 34.2 to 34.5). As an example, mature puss caterpillars are covered with gray to brown hairs, under which are stiff spines that are attached to glands that contain poison. When touched, these spines break off in the skin, where they cause severe pain. Eye disease has also been linked to this type of contact (6, 9).

Tick-induced paralysis is also seen and is caused by the injection of toxin from gravid female ticks embedded

TABLE 35.2 Vector-borne human infections

Type of infection and disease	Causative agent	Vector (common name)
Protozoal infections		
Malaria	*Plasmodium* spp.	Mosquitoes
Leishmaniasis	*Leishmania* spp.	Sand flies
Chagas' disease	*Trypanosoma cruzi*	Triatomid bugs
East African trypanosomiasis	*T. brucei rhodesiense*	Tsetse flies
West African trypanosomiasis	*T. brucei gambiense*	Tsetse flies
Babesiosis	*Babesia* spp.	Ticks
Helminthic infections		
Filariasis	*Wuchereria bancrofti*	Mosquitoes
Filariasis	*Brugia malayi*	Mosquitoes
Filariasis	*Dirofilaria* spp.	Mosquitoes
Filariasis	*Mansonella perstans*	Biting midges
Filariasis	*M. streptocerca*	Biting midges
Filariasis	*M. ozzardi*	Biting midges
Onchocerciasis	*Onchocerca volvulus*	Blackflies
Loiasis	*Loa loa*	Deerflies
Dog tapeworm infection	*Dipylidium caninum*	Dog lice, dog fleas, human fleas
Rat tapeworm infection	*Hymenolepis diminuta*	Rat fleas, beetles, grain beetles
Dwarf tapeworm infection	*Hymenolepis nana*	Grain beetles (rare)

in the flesh of the host. A review of 33 cases of tick-induced paralysis in Washington State showed that most of the patients were female (76%) and most cases (82%) occurred in children younger than 8 years; two of the children died (10). Onset of illness occurred over a 3-month period, and nearly all cases indicated probable exposure east of the Cascade Mountains. Of the 28 patients for whom information was available, 54% were hospitalized. When tick identification to species was reported, *Dermacentor andersoni* was consistently reported. Certainly tick-induced paralysis is a preventable cause of illness and death, and if diagnosed early, it requires simple, low-cost intervention (tick removal).

Stinging arthropods can be found in the following groups: Hymenoptera (ants, bees, hornets, and wasps) and the Scorpiones. Individuals vary in their reaction to these stings; anaphylaxis has been seen in cases related to bee stings. The frequency of mass bee attacks has dramatically

TABLE 35.3 Summary of direct effects of arthropods on humans and domestic animals[a]

Condition	Direct/harmful effects	Arthropods
Delusional infestation (parasitosis)	Irrational or destructive behavior	None; often imagined to be skin-invading ectoparasites
Entomophobia/Arachnophobia	Accidents caused by unusual fear of arthropods	Often involve spiders or members of the Hymenoptera (bees, wasps, and relatives)
Physical nuisance	Stress, mental anguish, reduced productivity	Any abundant arthropod that interferes with normal living conditions and/or activities
Contact irritation	Asthma or other respiratory allergies	Any abundant or domestic arthropod that produces airborne allergens
Feeding annoyance and blood loss	Pain, anemia, itching, and other cutaneous allergic reactions; stress, reduced fitness, and death	Temporary and permanent ectoparasites
Envenomization	Prolonged pain, inflammation, cyto/neurotoxic symptoms; anaphylactic allergic symptoms, including death	Arthropods with toxic stings, bites, setae, hemolymph, defensive secretions; usually bees, wasps, ants, spiders, or scorpions
Myiasis	Prolonged pain, tissue and fluid loss, secondary infection, reduced fitness, death	Larval diptera (e.g., *Dermatobia*, *Gasterophilus*, *Hypoderma*, *Oestrus*, *Calliphora*, *Wohlfahrtia*, *Sarcophaga*)

[a] Adapted from references 1–8.

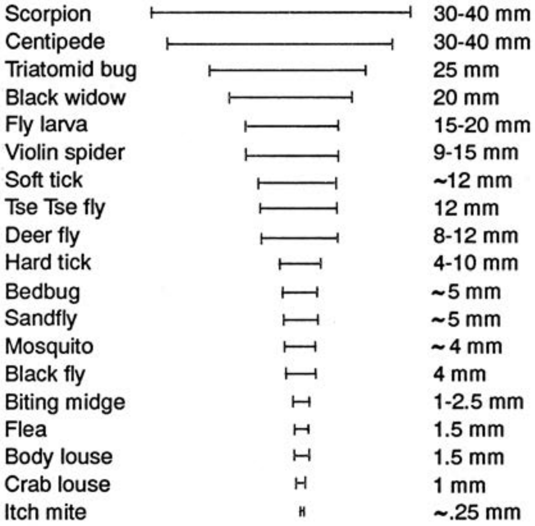

Figure 35.1 Relative sizes of various arthropods. (Illustration by Sharon Belkin.) doi:10.1128/9781555819002.ch35.f1

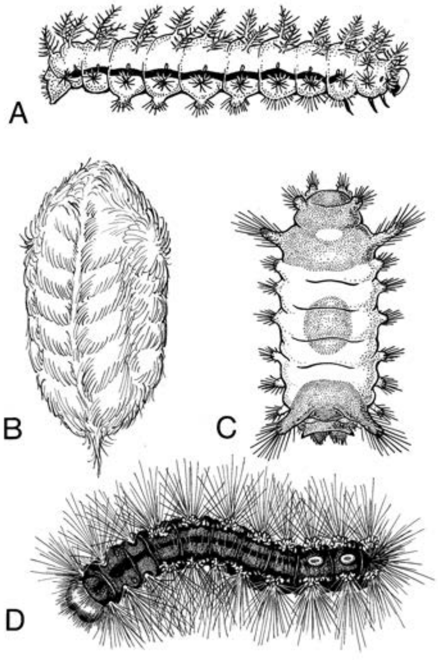
increased in the Americas following the introduction and spread of the aggressive Africanized "killer" bee (*Apis mellifera scutellata*). Currently there is no specific therapy available. However, an antivenom for the treatment of mass bee attacks has been developed. Venoms from European and Africanized bees appear to be very similar, if not identical (11). Scorpion stings are usually no more severe than bee stings; however, there are exceptions, and each year there are numerous deaths in Mexico as a result of scorpion stings. The venom is thought to be a toxalbumin that affects the nervous and pulmonary systems.

Some millipedes produce secretions that can cause contact vesicular dermatitis. These fluids can be squirted from glands located on the body segments. Blister beetles can also produce these types of fluids, leading to skin blisters within hours after contact.

Although death is rarely attributable to these types of injuries, small children and the very old may demonstrate severe reactions to both arthropod bites and stings.

Figure 35.2 Caterpillars that sting (A and B) or cause dermatitis (C and D). (A) Io moth, *Automeris io*; (B) puss caterpillar, *Megalopyge opercularis*; (C) saddleback caterpillar, *Sibine stimulea*; (D) brown tail moth, *Euproctis chrysorrhoea*. (Illustration by Sharon Belkin.) doi:10.1128/9781555819002.ch35.f2



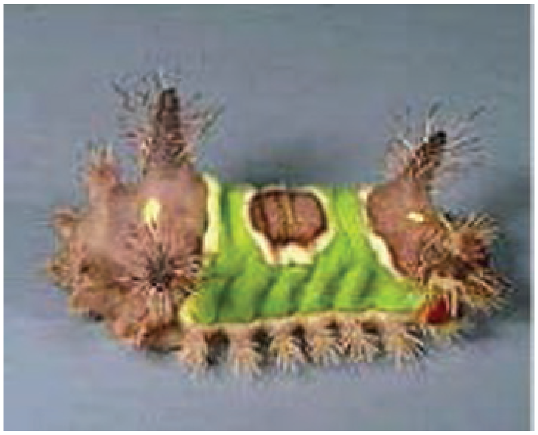


Figure 35.3 Saddleback caterpillar (*Sibine* sp.), which may cause dermatitis and necrosis. The irritant is in the barbed rigid nettling hairs. (Courtesy of R. Bessin, University of Kentucky: http://www2.ca.uky.edu/entomology/entfacts/ef003.asp.) doi:10.1128/9781555819002.ch35.f3

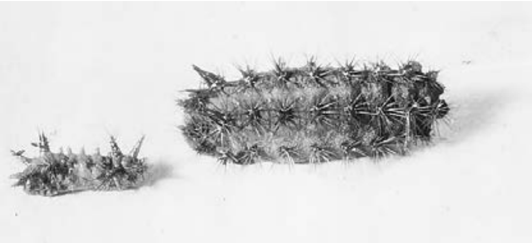
Figure 35.4 Caterpillars: *Monema flavescens* (left) and *Parasa* sp. (right). The small knobs on the body segments carry the stinging hairs, which are too small to be seen in the photograph. (Armed Forces Institute of Pathology photograph.) doi:10.1128/9781555819002.ch35.f4



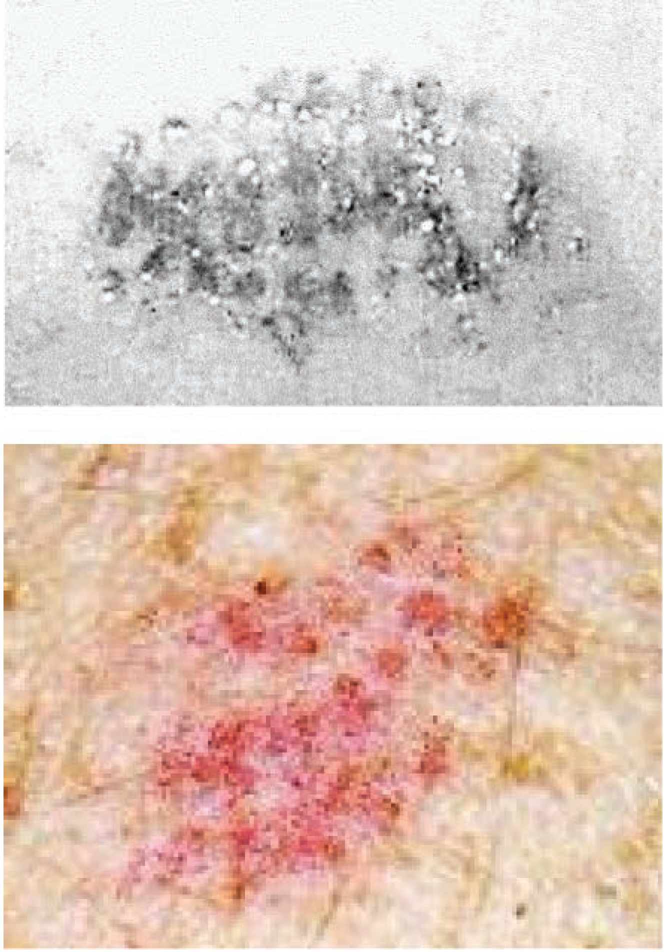


Figure 35.5 *Megalopyge opercularis*, the puss caterpillar. (Upper) Dermatitis is caused by venom introduced into human skin by hollow larval poisonous spines and occurs 24 h after exposure. (Lower) Puss caterpillar sting; note the ecchymosis outline matches the caterpillar's spines and remains visible for several weeks. The initial sting causes intense pain for more than an hour. (From *A Pictorial Presentation of Parasites:* a cooperative collection prepared and/or edited by H. Zaiman.)
doi:10.1128/9781555819002.ch35.f5

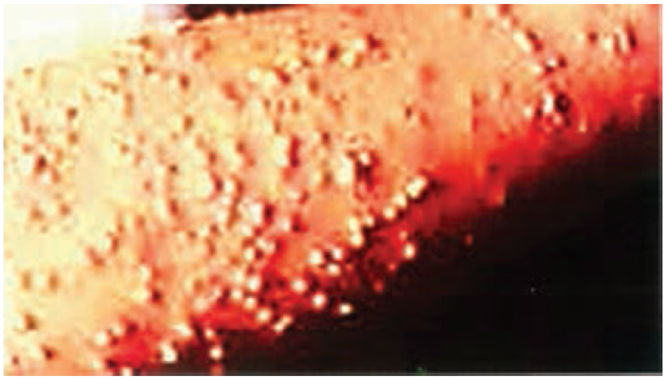

Figure 35.6 Severe reaction to multiple stings from a fire ant, *Solenopsis invicta*, on the arm of a male in Mississippi. (Armed Forces Institute of Pathology photograph.)
doi:10.1128/9781555819002.ch35.f6

The fire ant, *Solenopsis invicta*, is an example of an arthropod that has proven to be relatively dangerous, particularly in certain patients; the stings cause a fiery, burning sensation (Fig. 35.6). Severe allergic reactions, particularly in children, may require immediate attention. In the southeastern United States, the continued spread of these ants has caused agricultural problems, changes in the ecosystem, and increasing numbers of people with sting sequelae, including hypersensitivity reactions, secondary infections, and rare neurologic problems. Apparently, evolutionary changes have facilitated their expansion northward into Virginia and westward into California; further expansion is anticipated (12). Because of their resistance to natural and chemical control, fire ants can overwhelm their environment, causing destruction of land and animals. They can also cause a variety of health problems in humans, ranging from simple stings to overwhelming anaphylaxis and death. Although deaths caused by imported fire ant stings are rare, they may become more common as the fire ant population expands (13). Two alkaloid components of imported fire ant venom cause cardiorespiratory depression and elicit seizures in rats. Such effects identify these alkaloids as toxic compounds and may explain the cardiorespiratory failure seen in some individuals who experience massive fire ant stings (14).

S. invicta and *Solenopsis richteri* are not the only ant species to cause serious allergic or adverse reactions. Ant species belonging to six different subfamilies (*Formicinae*, *Myrmeciinae*, *Ponerinae*, *Ectatomminae*, *Myrmicinae*, and *Pseudomyrmecinae*) and 10 genera (*Solenopsis*, *Formica*, *Myrmecia*, *Tetramorium*, *Pogonomyrmex*, *Pachycondyla*, *Odontomachus*, *Rhytidoponera*, *Pseudomyrmex*, and *Hypoponera*) have this capability. Awareness that species other than imported fire ants may cause severe reactions should lead to more rapid patient evaluation and treatment (15).

Tissue Invasion

A number of arthropods are capable of actual tissue invasions, some of which may occur in the superficial tissues and some in deep body sites. These groups include Acari (ticks and mites), Diptera (flies, mosquitoes, and biting midges), Pentastomida (tongue worms), and Siphonaptera (fleas). The pentastomes are wormlike parasites that are related to the arthropods. On ingestion of eggs by humans, larvae migrate to the tissues, where they develop into nymphs and become encapsulated. Although most of these infections are asymptomatic, clinical manifestations can occur and include inflamed and enlarged lymph nodes, abdominal pain, jaundice, and ocular lesions (see chapter 29).

Various ticks, mites, and fleas tend to invade tissues at the superficial levels; these include *Sarcoptes scabiei* (itch mite), *Tunga penetrans* (chigoe flea), and members of the *Argasidae* (soft ticks) and the *Ixodidae* (hard ticks). Not only do these arthropods cause painful bites, but also they are responsible for transmission of diseases caused by bacteria, viruses, and rickettsiae.

When we consider arthropod tissue invasion, we usually think of myiasis, i.e., infestation with fly larvae (maggots). Clinically, myiasis is often categorized according to the part of the body invaded: cutaneous, mucocutaneous, intestinal, and genitourinary. Some larvae develop only in living tissue, while others prefer dead or necrotic tissue. Entry sites for egg or first-stage larva deposition can include unbroken skin, open wounds or lesions, nose or ears, mouth with subsequent swallowing, and genitourinary openings. There are three general groups of myiasis-causing flies: (i) those that require a host for the development of their larval stages, (ii) those that develop in a host if entry occurs via wounds or sores but development in a host is not required, and (iii) those that accidentally invade a host but generally complete larval development without a host.

Entomophobia and Delusional Infestation (Parasitosis)

Fear of insects, entomophobia, is sometimes seen and may become an issue in mentally disturbed individuals (1). These patients may report insect infestations, describing in great detail the presence of tiny insects in or on the skin. Symptoms may be described as crawling or biting sensations and are often accompanied by excessive scratching by the patient.

Delusional parasitosis usually represents a more serious emotional disorder in which patients believe that they have parasites in or on the body. It is also called the Ekbom syndrome after the Swedish neurologist Karl Axel Ekbom, who did extensive work on this syndrome. This name, however, is ambiguous and not recommended, because it is also used to refer to restless legs syndrome.

Delusional parasitosis can be primary, secondary, or organic. Primary delusional parasitosis consists of a single delusional belief of having been infested by a parasite and comes under monosymptomatic hypochondriacal psychosis. Secondary delusional parasitosis can occur in the context of other mental disorders like schizophrenia, depression, and dementia. Organic delusional parasitosis occurs secondary to organic illness, such as hypothyroidism, vitamin B_{12} deficiency, diabetes, cerebrovascular disease, cocaine intoxication, HIV infection, allergies, and menopause. These patients often describe many physician visits and consults with unproductive results; laboratory findings are consistently negative. They are absolutely convinced that they have legitimate problems and continue to try to get confirmation of problems that are imaginary rather than real. They tend to bring in small bits and pieces of skin or debris, pictures, drawings, etc., none of which demonstrate true infestation. Often, these bits and pieces of debris are of nonanimal origin (string, paper, plant material, etc.). We have received complete notebooks filled with 8-by-10-in. photographs of “parasites”—none of which depict anything that can be recognized as possible arthropods or any other type of parasite. Morgellons, which refers to cutaneous symptoms like biting, crawling, or stinging sensation, finding fibers on or under skin, and persistent skin lesions, is often seen in delusional parasitosis (16).

In recent years, patients have reported the presence of specific parasites less commonly, and the name delusional parasitosis thus has the disadvantage of covering only one group of pathogens. The broader term “delusional infestation” has been recommended as the future designation. This name highlights the core psychopathological feature (a thought disorder) and covers all kinds of (even “newly emerging”) imaginary pathogens by referring to the delusional theme “infestation” and not to a single species.

These patients search out specific medical professionals, often by making multiple telephone calls and calling medical and other scientific societies. Unfortunately, they can benefit only from psychiatric treatment. However, patients with delusions of parasitosis generally reject psychiatric referral. The diagnosis of delusions of parasitosis can often be made on the basis of the history alone, but it is important to ensure that the patient does not have an organic skin disorder and that the delusion is not secondary to another mental or physical illness.

Specimens are usually presented in a small bin, vessel, bag, piece of paper, or plastic foil to protect the “pathogens.” Usually, the patients handle these allegedly dangerous pathogens without disgust or anxiety. Instead, they are collected and stored like trophies. The “pathogens” usually consist of materials, such as dander, crusts, scabs from healing skin lesions, hair, threads and other particles from clothes, fibers, dirt, sand, arthropod parts, or breadcrumbs. More and more patients present digital photos or movies.

Patients ask the physician for an extensive diagnostic work-up, no matter how many previous dermatological and microbiological tests were unremarkable with negative results. These patients will not be “relieved” by negative findings. Instead, “nonfindings” will be interpreted as “incompetence” of the doctor, or patients will find another explanation to maintain their beliefs (e.g., “the sample was taken at the wrong site or the wrong time; a bad microscope, wrong medium, or wrong analytical method was used; a mix-up of samples, names, or reports occurred,” and others). Many patients request additional therapy rather than more diagnostic testing. They “already know” what they have and often ask to be prescribed the most aggressive antibiotic, virucide, pesticide, or other medication to get rid of the pathogens.

In spite of these psychiatric problems, it is still appropriate to check all possibilities: bites from unrecognized mites or other insects, either at home or in the workplace, or potential exposure to other allergic stimuli that may be unrelated to insect or organism contact needs to be considered. Unfortunately, in many of these patients, the presentation is so convincing that it is difficult at first to recognize the situation as a mental rather than actual physical problem. For adequate therapy, interventions at all steps of the cycle are required, including local skin therapy to reduce itch, the prevention of further manipulations, and sufficient antipsychotic treatment of the fixed belief.

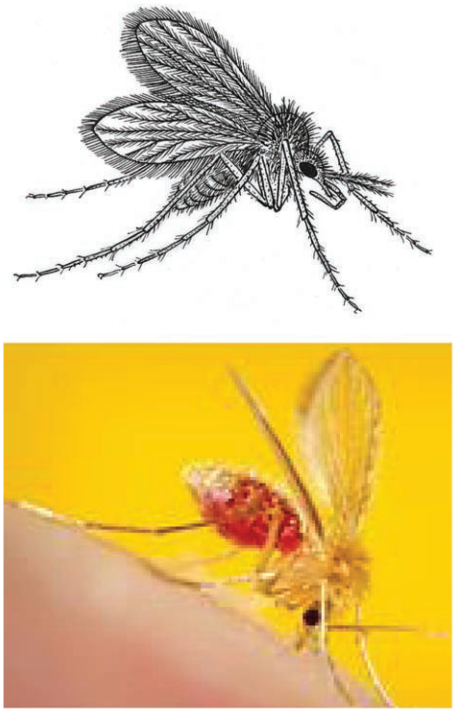

Figure 35.7 Sand fly (*Phlebotomus* and *Lutzomyia* spp., vectors of *Leishmania* spp.), ~5 mm. (Upper, illustration by Sharon Belkin; lower, color image courtesy of the CDC Public Health Image Library.) doi:10.1128/9781555819002.ch35.f7

Class Insecta (Insects)

Some of the more important orders are presented in this section. Adults have a segmented body composed of the head, thorax, and abdomen; one pair of antennae; three pairs of legs; and, in some cases, wings. The exoskeleton is composed of hard plates (sclerites) separated by flexible membranes (conjunctivae or arthrodial membranes) or grooves (sutures).

Order Diptera (Flies, Mosquitoes, and Midges)

The order Diptera contains numerous kinds of flies, mosquitoes, and midges. The members of this group have two pairs of wings, one pair of which, the halteres, are vestigial and are used for balance only.

Sand Flies (Leishmaniasis)

Species of the genus *Leishmania* (Kinetoplastida *Trypanosomatidae*) are the causative organisms of leishmaniasis, and these parasitic unicellular protozoans are usually transmitted between vertebrate hosts by the bite of bloodsucking female phlebotomine sand flies. Sand flies occur mainly in the tropics and subtropics, limited to areas where the temperatures are above 15.6°C for a minimum of 3 months of the year. They are found in a number of habitats, from below sea level to 2,800 m above sea level or higher. Sand flies are small, long-legged flies that are about 5 mm long (Fig. 35.7). These small flies are able to pass through ordinary mosquito netting. Two genera (*Phlebotomus* in the Old World and *Lutzomyia* in the New World) are of medical importance. Only the females feed on blood, usually that of mammals; such feeding normally occurs at night. The bite site is usually indurated and inflamed, with a wheal 1 to 2 cm in diameter, and is accompanied by pruritus. Some patients even respond with a systemic allergic reaction, including fever, nausea, and malaise. Although many sand flies can fly extended distances, they usually move in short, jerky hops along walls and ceilings. Spraying with residual insecticide is somewhat effective; however, elimination of larval habitats would be a more important control measure.

Sand flies are a geologically old group, being identified from about 120 million years ago, prior to the origin of mammals. They probably originally fed on reptiles, and their ancient status led to the evolution of different groups in the New and Old Worlds. Their main importance is as vectors of *Leishmania* spp., causing human cutaneous, mucocutaneous, and visceral disease. About 80 of 700 known sand fly species are known vectors of *Leishmania* spp. Two species of *Lutzomyia* occur in south and central Texas, as well as parts of Mexico, and are probably the vectors of cutaneous leishmaniasis in Texas. It is interesting that lectins and toxins in the plant diet of *Phlebotomus papatasi* can kill *Leishmania major* promastigotes in the sand fly and in culture; these vegetation components may decrease parasite transmission in certain areas (17). Control measures against the adult flies include the use of the bacterial insecticide *Bacillus thuringiensis* (18).

Sand flies are small (<5 mm long) and fragile. These tiny, densely haired flies tend to rest with their wings held upward at 60°. This resting appearance, along with a dark-gray to dusty-brown color, large eyes, mouthparts at least as long as the head, long antennae, long palpi, and a fuzzy appearance, provide excellent clues for identification. Females have a plump, cylindrical abdomen, somewhat tapered distally, which appears to end with two rounded, paddle-like segments (cerci). There are a total of six genera, *Phlebotomus*, *Sergentomyia*, and *Chinius* in the Old World and *Lutzomyia*, *Brumptomyia*, and *Warileya* in the New World; *Phlebotomus* and *Lutzomyia* are the two most common genera. In addition to sugars from plants, females require one or more blood meals for each batch of eggs. Sand fly bites tend to be quite painful. The use of insecticides, protective clothing, and clothing/bednets treated with permethrin will reduce contact with sand flies. In arid regions of the Middle East that are inhabited by colonial rodents, deep plowing over concentrations of burrows tends to reduce *Leishmania major* reservoirs and vector habitats (5).

There is evidence of an increasing range of sand fly species, especially for the Atlantic Coast and inland parts of Germany, Switzerland, and Austria. The most important and urgent necessity within the community of entomologists working on phlebotomines is the need to record the extremes of distribution of each species and obtain data on their regional presence/absence along with increased sharing of the data throughout European projects.

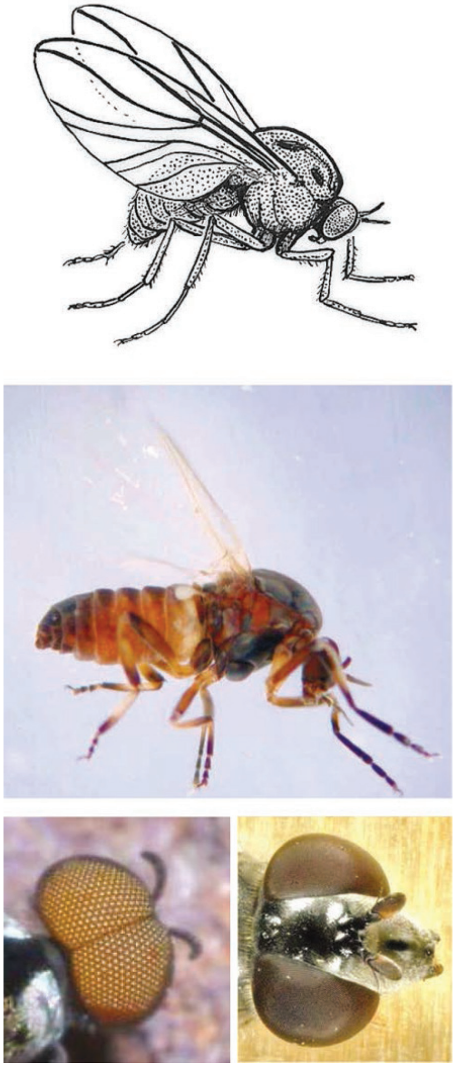

Figure 35.8 Blackfly (*Simulium* sp., vector of *Onchocerca volvulus* and *Mansonella* spp.), ~4 mm. (Top, illustration by Sharon Belkin; middle, color image courtesy of A. Blackflies (Filariasis [*Onchocerca* and *Mansonella* spp.])

Blackflies (buffalo gnats, turkey gnats, Kolumbtz flies) transmit *Onchocerca volvulus* worldwide; in the Old World these vectors are limited to Africa, while in the New World the vectors are found in various parts of Central and South America. Blackflies are small flies (*Simulium* spp.) measuring 1 to 5 mm long and usually having a stout body and humped back (Fig. 35.8). Only the females suck blood, and swarms may attack humans as well as domestic and wild mammals, usually during the daytime. The blood meal is required for egg development. Although not usually that painful, the bite is accompanied by intense itching and the development of a raised, ulcerative lesion at the site, most probably caused by the saliva in the puncture wound. Individuals who are particularly susceptible may experience severe pruritus and body swelling (blackfly fever), which is seen predominantly in children in rural areas of the northeastern United States. Similar to Hymenoptera, a Simuliidae bite occasionally results in extreme hypersensitivity and should be considered in appropriate cases.

These flies normally do not bite indoors and may fly long distances from their habitats. A massive control effort is now under way in West Africa to lower the intensity of *Onchocerca* transmission to a level of infection that does not lead to visual impairment. Because flight distances are long and the larvae develop in water, control measures are difficult at best. Simuliids breed in running water, ranging from torrential mountain streams to slow-moving lowland rivers, and a few species adapt to streams with little perceptible current. Development occurs in fast-running streams, often very deep; one species was found breeding at depths down to 190 ft (ca. 50 m). Adult appearance occurs predominantly in the daytime, depending on light and temperature. In *S. damnosum* 60–90% of the day's activities occur by midday and there is no emergence at night.

Simuliids have to survive periods when the temperature is too low to sustain routine activities and when the rivers dry up during the off season. They can apparently reduce their respiratory rate and replace trehalose in the hemolymph by high polyhydric alcohols, thus remaining dormant below 4°C. Once the temperature rises, the reverse process is rapidly completed and growth resumes. These flies may not be present in sufficient numbers to be pests, but they can still be important vectors of the filarial worm causing onchocerciasis or "river blindness."

The biting preference of *Simulium* vectors (buffalo gnats) has been known to influence the distribution of *Onchocerca* nodules and microfilariae in the human body. In Africa, *S. damnosum and S. neavei* have been reported to tend to bite in the ankle region, thus resulting in a higher density of nodules and microfilariae in the lower part of the body, whereas in central America, *S. ochraceum* bites mostly in the head and neck regions, producing a higher density of nodules and microfilariae in the upper body.

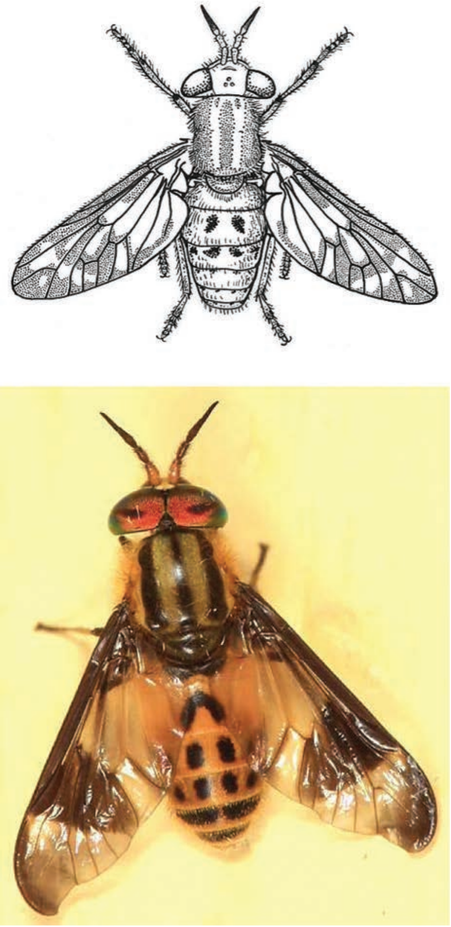
In Brazil, black fly saliva was determined to be responsible for pemphigus foliaceus, also known as bulbous autoimmune disease or wild fire disease. It was also named as the cause of death in immigrants suffering from Altamira hemorrhagic syndrome, which is characterized by hemorrhage of the skin around the bites (multiple petechiae and ecchymosis), bleeding mucosa, and anemia. Female black flies exhibit pool feeding behavior, in which salivary proteins injected at the injury site maintain the blood meal in a fluid state. These proteins include anticoagulants, vasodilators, and modulators of platelet aggregation (19).

The adult *Simulium* is characterized by a small, rounded body, bead-like antennae, an arched thorax, and a pair of wings that span 6 to 10 mm with thickened veins near the leading edge. Most flies are black in color but some species may be orange or yellow. The male's eyes are holoptic (meeting along the dorsal length of the head) (Fig. 35.8), while the female's eyes are dichoptic (separated by an anterior segment called the frons). Ventral on the head is the mouth, a complex structure marked by two maxillary palps attached near the base of the proboscis. The labium forms the back of the proboscis and envelops the other parts of the mouth, which include the serrated mandibles and the toothy posterior maxilla called the laciniae. The color patterns of the legs and thorax can be useful in species identification of *Simulium*.

Deer Flies (Filariasis [*Loa loa*])

Adult flies (*Chrysops* spp.) are medium sized to large (about the size of a housefly or larger) and stoutly built, with large eyes and dull-colored bodies (Fig. 35.9). Only

Figure 35.9 Deerfly (*Chrysops* sp., vector of *Loa loa*). (Upper) Female, 8 to 12 mm (illustration by Sharon Belkin). (Lower) Male, color image (courtesy Tom Murray, http://wiki.bugwood.org/File:Chrysops_tom_murray.JPG).
doi:10.1128/9781555819002.ch35.f9



the female is adapted to take a blood meal. Adult males and females will take nectar, and some are specially adapted for drinking from deep flowers by using a long proboscis. However, most females use their blade-like mandibles to slice into skin, drinking the blood that pools in the cut. The bite site can become a painful wound that takes a long time to heal; individuals may also respond with an allergic reaction to the saliva of the fly. A person can become increasingly sensitive to repeated bites.

Day-biting flies transmit the human form of disease with *L. loa*, a disease that affects up to 13 million people. This biting time preference coincides with the peak microfilaremia in humans. The adult flies live high in the forest canopy and descend to the forest floor to feed on humans. While most blood-sucking insects are repelled by wood fire smoke, apparently in Africa the flies are attracted to wood fires. Control measures have not been particularly successful, and loiasis continues to be a significant problem in West Africa.

Deer flies are slightly larger than house flies and mostly yellow or black with darker stripes on the abdomen and dark markings or patterns on the wings. They have thick, elongate antennae and brilliant green or golden eyes with zigzag stripes.Males are holoptic (eyes large and touching) while females are dichoptic (normal eyes). All have a distinct wing venation where the R4+R5 vein encloses the tip of the wing. Characters on the face and coloration/patterns may be helpful in identifying these flies to the species level.

Tsetse Flies (African Trypanosomiasis)

An estimated 60 million people are at risk for African trypanosomiasis, with 300,000 to 500,000 new cases each year, primarily in the Democratic Republic of Congo, Angola, and Sudan. Tsetse flies (*Glossina* spp.) are robust, honey-brown flies measuring 6 to 15 mm long (the size of a housefly) (Fig. 35.10). The genus habitat is limited to the African continent south of the Sahara. Both sexes are voracious blood feeders, and both can transmit parasites. Adult flies of the important vectors are daytime feeders and are attracted to moving animals and humans. The flies use movement and smell to find appropriate hosts. Although they can fly long distances, their flight pattern is generally limited to the closest available host and back to particular vegetation, where they spend long periods of rest. The wings have the characteristic "hatchet" cell, which is cleaver shaped (Fig. 35.10).

Tsetse flies are diurnal and only active between the temperatures of 18 and 32°C. They feed primarily on suids and bovids, but blood from animals as diverse as monitor lizards and hippopotami has been found in their guts. There is no sexual dimorphism in their feeding habits, except that the female must eat more to sustain the large larvae during pregnancy. They respond to CO_2 produced by the exhalation of animals. Both sexes feed exclusively on blood and produce anticoagulants to prevent clotting. They find their targets through sight and smell. They suck blood every 2 to 3 days, and each blood meal lasts 1 to 10 minutes. Flies are active only for about 1 hour a day. In the meantime they rest in the surrounding vegetation.

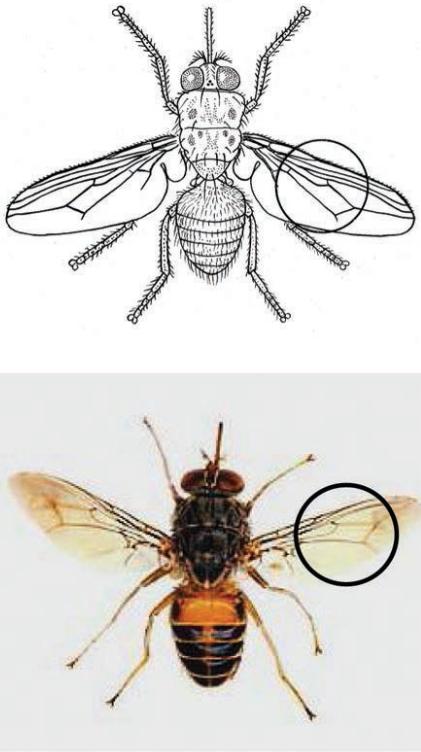


Figure 35.10 Tsetse fly (*Glossina* sp., vector of African trypanosomes). (Upper) Female, ~12 mm. The characteristic "hatchet" cell is seen within the circle. (Illustration by Sharon Belkin.) (Lower) Color image (courtesy of the Universidade Federal do Rio Grande do Sul, Faculdade de Veterinaria, Daniele Focosi, http://www.ufrgs.br/imunovet/molecular_immunology/sitemap.html). doi:10.1128/9781555819002.ch35.f10

Adult females do not lay eggs but are larviparous, i.e., the eggs hatch inside the uterus, where they are nourished with the secretions of a specific gland. There is always only one larva developing in the uterus. It needs about 10 days to reach maturity (stage III). Then the female deposits the larva on dry soil below the vegetation. The larva crawls into the soil and pupates without further feeding. The pupal stage lasts 3 to 13 weeks. An adult fly lives for about 3 months. There are about four generations a year.

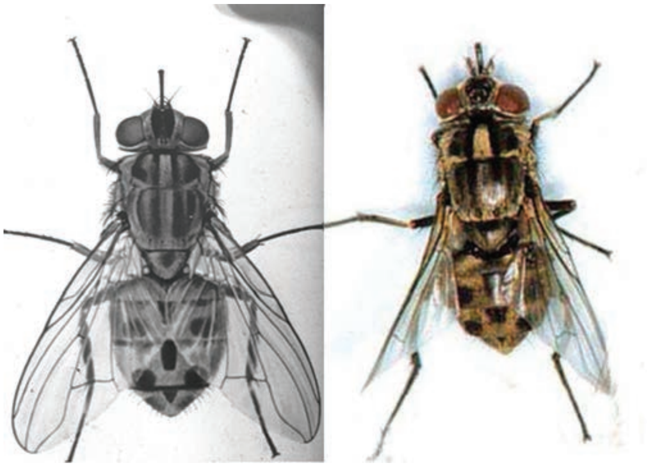
The adults are long-lived and fly long distances, usually along a preferred flight line; they live in areas called fly belts. Some species live by rivers, and others are found in the savanna. They feed on many animals as well as humans. This fact, along with their long life span, makes vector control difficult; it sometimes involves such drastic measures as killing off game animals in close proximity to humans or moving whole villages out of these fly belts. The use of insecticides has also proven to be somewhat successful. Wherever there are tsetse flies, it is impossible to keep cattle without regular chemotherapy. Trypanosomiasis has inhibited or totally prevented the development of a cattle-raising industry in much of tropical Africa. Currently, cattle ranches are still impractical in the savanna areas of Africa. Also, there is increasing resistance to melarsoprol, the key drug for central nervous system involvement in African trypanosomiasis.

Stableflies, Houseflies, and Horseflies (Potential Carriers of Infectious Organisms)

Stableflies. Flies in the genus *Stomoxys* (stableflies) (Fig. 35.11) resemble the housefly. Both male and female flies can be tremendous pests, with an impressive bite (causing a stabbing pain) which involves ripping open the skin, through which the biting apparatus is inserted. They measure about 6 or 8 mm long and have four distinct, dark longitudinal stripes on the thorax and several dark spots on the abdomen, with sharp mouthparts protruding from the head. Along the southeast coast of the United States, these flies breed in decaying seaweed and can be a tremendous tourist problem during fly season. There is low host specificity, although they feed mainly on the blood of cattle and horses. Adults locate a host by sight, and feeding is usually completed in 2 to 5 minutes.

Although control of the larvae has been difficult, insecticides are effective against the adult flies. Residual insecticides are initially effective, but these flies rapidly develop resistance. The stablefly breeds in a number of habitats commonly found in agricultural areas such as decaying straw, oats, rice, barley, wheat, silage, horse manure, lot manure (manure from pig farms), and cow manure.

Figure 35.11 Stablefly (*Stomoxys* sp.), 6 to 15 mm long. (Left photograph courtesy of Duane J. Gubler, Centers for Disease Control and Prevention; right image courtesy of Jim Kalisch, University of Nebraska-Lincoln, Dept of Entomology, http://entomology.unl.edu/images/muscidflies/.)
doi:10.1128/9781555819002.ch35.f11



Houseflies. Houseflies can be easily identified by the four dark, longitudinal stripes on top of the thorax, or middle body region. They vary in length from one-eighth to one-fourth of an inch. Their mouth parts are adapted for sponging up liquids; they cannot bite and can only ingest liquid food. They feed on solid food by regurgitating saliva on it. The saliva liquifies the solid material which is then sponged up with the proboscis. These flies require water since they are continually salivating and voiding liquids. Fly specks seen on many surfaces visited by houseflies are the excreted wastes. Houseflies can harbor >100 different pathogens, most of which can be transmitted. They range from viruses to helminths and include protozoan cysts, oocysts, spores, and helminth eggs. There are several ways in which houseflies can disseminate pathogens. The surface of the body can be contaminated; pathogens can be regurgitated onto food through the fly's vomit drop; or pathogens can pass through the gut of the fly and be deposited in its feces.

Horseflies. Horseflies are blood-sucking insects that can be serious pests of cattle, horses, and humans. Horseflies range in size from three-quarters of an inch to 1 1/4 inches long and usually have clear or solidly colored wings and brightly colored eyes. Female horseflies are active during the day. They are attracted to such things as movement, shiny surfaces, carbon dioxide, and warmth. Once on a host, they use their knife-like mouthparts to slice the skin and feed on the blood pool that is created. Bites can be very painful, and there may be an allergic reaction to the salivary secretions released by the insects as they feed. Like mosquitoes, female horseflies must ingest a protein-based blood meal before they can reproduce. Most horseflies will avoid people who are using insect repellent. A high-quality insecticide sprayed on the body or around the nearby area usually wards off these insects. Repellents containing diethyltoluamide or DEET are particularly effective.

It is interesting that in areas such as northern Africa where tsetse flies are not found, domestic animal trypanosomes, *T. evansi* and *T. vivax vivax*, are transmitted mechanically by horseflies (*Tabanus*) and stableflies (*Stomoxys*). These flies can spread trypanosomes within domestic animal herds, causing epidemics with tremendous financial loss.

Biting Midges (Filariasis [*Mansonella* spp.])

Biting midges (*Culicoides* spp.) are the smallest of the biting flies, measuring between 1 and 4 mm (Fig. 35.12). They are also known as "punkies," "no-see-ums," "gnats," or

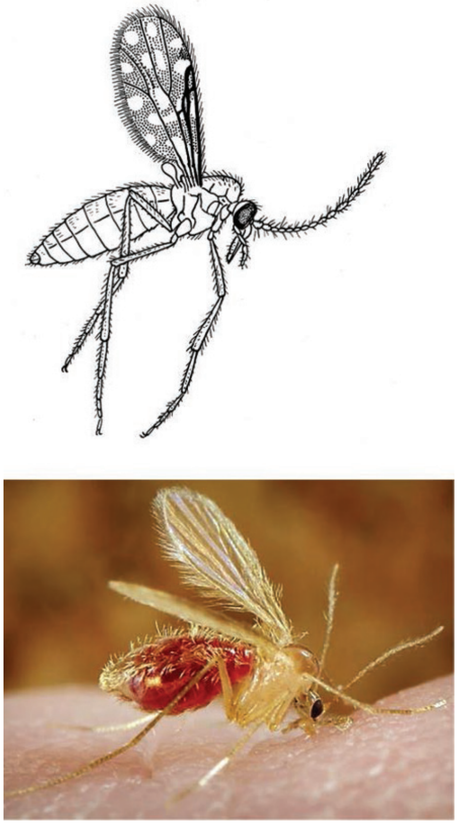


Figure 35.12 Biting midge (*Culicoides* sp., vector of *Mansonella* spp.), 1 to 2.5 mm (usually 1 to 4 mm long). (Upper, illustration by Sharon Belkin, adapted from Faust EC, Russell RF, June RC [ed], *Clinical Parasitology*, 8th ed, Lea & Febiger, Philadelphia, PA, 1970; lower, color image courtesy of the CDC Public Health Image Library.) doi:10.1128/9781555819002.ch35.f12

"flying teeth." Only the females feed on blood, and swarms may attack humans or other mammals, usually at dusk, when the air is still. The bites of biting midges inflict a burning sensation and can cause different reactions in humans, ranging from a small reddish welt at the bite site to local allergic reactions that cause significant itching. Screen and netting controls are difficult because of the small size of the adult fly.

Male and female biting midges feed on plant sap and nectar, the primary energy sources for flight and for increased longevity of females. Egg production requires a protein source, which is obtained either from the body fluids of small insects or from vertebrate blood. Male biting midges are not attracted to vertebrates, and their mouthparts are not capable of biting.

The genus *Culicoides* is widely distributed throughout the world and ranges from sea level to almost 14,000 ft in Tibet. Members of the 1921 Everest expedition complained of being bitten continually from base camp almost to the summit. These biting midges can cause acute discomfort, particularly on warm, humid days; in spite of their small size, the bite often produces a severe local reaction. Females make small cuts in the skin, and the saliva contains an anticoagulant. Once the blood pools, it is sucked up. It was calculated in the early 1980s that because of the tremendous number of bites to which a human can be subjected, a person spending 1 h per day on the beach in Trinidad in the early morning would receive 38 bites infective for *Mansonella ozzardi* in the course of a year. However, with the tremendous tourist industry impact, control measures are constantly being revisited.

Success in suppressing adult biting midges with insecticides is somewhat limited and only under certain conditions. The installation of window and door screens consisting of a mesh size smaller than normal window screen is much more effective in reducing bites because such screens prevent female biting midges from entering dwellings. Similarly, people camping in certain areas of the western United States should use tents outfitted with "biting midge screening" that consists of a mesh size smaller than normal window screening.

Mosquitoes (Malaria, Filariasis, and Arbovirus Infections)

Mosquitoes are slender, delicate insects that are distributed worldwide. There are over 2,500 different species, of which 150 species occur in the United States. All mosquitoes require water in which to complete their life cycle, which can vary in quality from melted snow water to sewage effluent and can be in any container imaginable. The type of water in which the mosquito larvae is found can be an aid to the identification of which species it may be. Also, adult mosquitoes show a very distinct preference for the types of sources in which to lay their eggs, e.g., such places such as tree holes that periodically hold water, tidewater pools in salt marshes, sewage effluent ponds, irrigated pastures, rainwater ponds, etc. Each species therefore has unique environmental requirements for the maintenance of its life cycle.

Only the adult females bite humans and other animals. The male mosquitoes feed only on plant juices. Some female mosquitoes prefer to feed on only one type of animal while others can feed on a variety of animals. Female mosquitoes feed on humans, domesticated animals, all types of birds including chickens, all types of wild animals, and various reptiles. The life span of the adult mosquito usually depends on several factors: temperature, humidity, sex of the mosquito, and time of year. Most males live about a week and females live about a month (Fig. 35.13). When biting with their proboscis, they stab two tubes into the skin: one to inject an enzyme that inhibits blood clotting, the other to suck up the blood.

Some species deposit eggs singly; some eggs remain single, while others are stuck together in rafts of 200 to

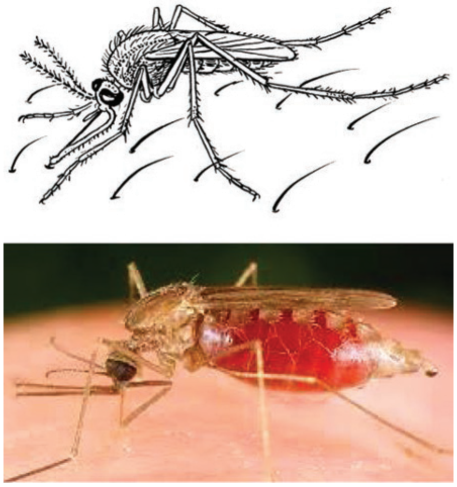

Figure 35.13 (Upper) Mosquito, ~4 mm (illustration by Sharon Belkin). (Lower) Female *Anopheles freeborni* mosquito taking a blood meal (courtesy of the CDC Public Health Image Library).

(Lower) *Culex* has a breathing tube, so that it lies almost perpendicular or at an angle to the surface of the water. Note other physiological differences between *Anopheles* and *Culex*. (Courtesy of the CDC Public Health Image Library.)
doi:10.1128/9781555819002.ch35.f14

300 eggs. Mosquito larvae, commonly called “wigglers” or “wrigglers,” must live in water from 7 to 14 days depending on water temperature. Larvae come to the surface at frequent intervals to obtain oxygen through a breathing tube called a siphon (*Culex*), while others lie parallel to the surface to obtain oxygen (*Anopheles*) (Fig. 35.14). During growth, the larva molts four times. The stages between molts are called instars. At the fourth instar, the larva reaches a length of almost a half inch. When the fourth instar larva molts it becomes a pupa.

Anopheles mosquitoes are the only mosquito which transmits malaria to humans; they also transmit filariasis and encephalitis. ***Aedes*** mosquitoes are painful and persistent biters, attacking during daylight hours (not at night). They do not enter dwellings, and they prefer to bite mammals like humans. *Aedes* mosquitoes are strong fliers and are known to fly many miles from their breeding sources. *Aedes* carry yellow fever, dengue, and encephalitis. ***Culex*** mosquitoes are also painful and persistent biters, but they prefer to attack at dusk and after dark and readily enter dwellings for blood meals. Domestic and wild birds are the preferred targets. *Culex* are generally weak fliers and do not move far from home, although they have been known to fly up to 2 miles. *Culex* live only a few weeks during the warm summer months. Those females which emerge in late summer search for sheltered areas where they “hibernate” until spring. Warm weather brings them out in search of water on which to lay their eggs. *Culex* mosquitoes carry encephalitis, filariasis, and West Nile virus.

Mosquitoes are the most important group of arthropods in terms of disease transmission and, as pests, produce an irritating dermatitis. To be effective vectors for malaria, female *Anopheles* mosquitoes must feed frequently on humans, must be relatively susceptible to the malarial gametocytes, must live long enough for the malaria parasite to complete the life cycle, and must be present in sufficient numbers to maintain transmission of the parasite. Blood feeding follows a circadian rhythm, with most species feeding at night or during the twilight hours, either right after sunset or before sunrise. The biting cycle has control implications, since mosquito nets are effective against nocturnal species, especially those that bite after midnight. Mosquitoes are not limited to ground level elevation, but in forests can be found from the surface up into the canopy where birds and primates live.

In the tropics, breeding usually continues throughout the year. Important species within the United States include *Aedes aegypti* (yellow fever, dengue fever), *Aedes albopictus* (yellow fever, dengue fever, LaCrosse encephalitis virus), *Ochlerotatus* (*Aedes*) *sollicitans* (Eastern equine encephalitis [EEE]), *Aedes vexans* (EEE), *Anopheles quadrimaculatus* (malaria in the eastern United States in the early 20th century), *Culex nigripalpus* (St. Louis encephalitis [SLE]), *Culex quinquefasciatus* (SLE, West Nile virus [WNV]), *Culex salinarius* (SLE, WNV, EEE), and *Culex* *tarsalis* (Western equine encephalitis [WEE], SLE). Mosquito-borne diseases cause millions of deaths worldwide every year, primarily in children and the elderly in developing countries.

Myiasis

Myiasis is the infestation of live human and vertebrate animals with dipterous larvae which feed on the host's dead or living tissue, liquid body substances, or ingested food (Tables 35.4 and 35.5). Maggots can infest any organ or tissue accessible to fly oviposition; most cases probably occur when a female fly lands on a human host and deposits either eggs or larvae. Human myiasis is found worldwide, with more species and greater abundance in poor socioeconomic regions of tropical and subtropical countries. In countries where it is not endemic, myiasis is an important condition, where it can represent the fourth most common travel-associated skin disease.

The order Diptera contains insects that are commonly known as true flies. The presence of a single pair of functional wings with a reduced hind wing, termed halteres, distinguishes true flies from other insects. There are approximately 150,000 species in 10,000 genera and 150 families. This order contains most of the insects transmitting diseases in humans.

Human infestations have been found in the breast, urinary bladder, colon, penis, gums, brain, carcinoma of the scalp, and various skin lesions (20–27). It is also important to realize that nosocomial transmission can occur; myiasis cases have occurred in hospital patients, often those who are debilitated (28–31). Specimens should be killed, preserved in hot (60°C) 70% alcohol, and then submitted to the laboratory for identification. Myiasis-producing members of the Diptera of medical importance can be seen in Tables 35.4 and 35.5.

For business or pleasure, more people than ever before are traveling throughout the world. Since 3 to 10% of these travelers experience skin, hair, or nail disorders related to their travels, it is more and more likely that Western physicians will be expected to treat exotic infections imported from different countries. Tungiasis and furunculoid myiasis are two typical disorders of intertropical regions. These are conditions induced by the presence of arthropod larvae or eggs in the skin. It will become more important for physicians to recognize these and other conditions, many of which they may have not seen previously.

In cases of myiasis, it is important to make the correct identification of the larva. This helps to clarify how the infestation was acquired, supports the treatment plan, and suggests preventive measures. After removal, the maggot should be killed by immersion for 30 s in very hot (enough to produce vapor) but not boiling water, which prevents decay and maintains the natural color. Larvae should then be preserved in a solution of 70% to 95% ethanol. Killing the larvae directly in a preservative tends to putrefy and shrink the specimen(s). Isopropyl alcohol (70%) can be used instead of 70% ethanol. Formalin is not recommended, because it causes excessive hardening of the larval tissues, making processing more difficult.

The identification of larvae found in human tissues is based on a number of morphologic characters, including (i) structure of the chitinized mouthparts, (ii) abdominal spiracles, and (iii) structures of the cuticle (these vary depending on the particular instar larva and the number of molts). Occasionally, if living mature larvae are submitted for examination, they can be held until they pupate and hatch; the adult flies can then be examined for identification. Doppler ultrasonography has also been used to evaluate the number of larvae present per lesion; this approach helps avoid misdiagnoses and treatment delays (32). An excellent Internet resource to help identify the species when a trained expert is not present is the Natural History Museum (London, United Kingdom) website (http://www.nhm.ac.uk/research-curation/research/projects/myiasis-larvae/intro-myiasis/index.html) (accessed 6/3/14) using the option, "launch the key to myiasis-causing larvae."

Pseudomyiasis refers to the accidental ingestion of dead or living fly larvae with no associated pathologic changes or symptoms. The term "sanguinivorous myiasis" has been used to refer to superficial attachment of larvae during blood sucking.

Medicolegal Forensic Entomology

Forensic entomology has become a recognized discipline that is concerned with the application of information on insects and other arthropods to legal issues. The most common applications deal with the determination of death, manner of death, movement of the corpse, and other aspects of the investigation. Insects occurring in carrion can be assigned to four groups. Those that feed on the carrion, including blowflies, arrive within a few hours of death. They are followed by species that feed on the body, species that feed on its inhabitants, and species that use the corpse as an extension of their natural environment. Various stages are identified in the decomposition of the corpse and are important in helping set the time of death: (i) autolytic and microbial decomposition, during which blowflies oviposit; (ii) active decomposition by insects; (iii) advanced decomposition, primarily by coleopteran beetle larvae; (iv) microbial decomposition, which takes over when coleopteran beetle larvae leave and ends in mummification; and (v) separation of the skeleton into individual bones, when the time of death can no longer be determined (20).

The entomologist must determine the time the insect attack began; many factors influence the confirmation of this time: cadaver location (whether it was exposed to sun or shade); whether the cadaver was covered, buried, or open to the elements; whether it was wet or dry; and ambient and ground temperatures. Often a pig is used to simulate the corpse conditions and to determine various rates of decomposition and insect activity; this is particularly helpful if conditions in a particular ecoclimate are not known.

Because the length of the oldest maggots recovered from a body often provides an accurate estimate of the time of death, it is important to ensure adequate fixation without subsequent shrinkage. Studies have shown that maggot shrinkage can lead to underage errors, thus leading to differences of many hours. It has been found that maggots killed in boiling water and then placed in appropriate preservatives do not shrink. The length of the larval crop, which can be useful in age estimates of postfeeding larvae, is not altered significantly when using this approach. Standardized handling and fixation of maggots at the crime scene are critical to valid and consistent interpretations (33).

It is also possible that fly pupae may contaminate forensic entomology samples at death scenes if they originate from animal carcasses or other decomposing organic material rather than from human remains. These contaminants may falsely increase postmortem estimates if no pupae or puparia are actually associated with the body (34).

To permit rapid identification of arthropods, random amplified polymorphic DNA typing has been used to support classic morphologic and forensic analysis of maggots found on a human corpse. This approach has been used to determine if maggots found on the body match those on the outside of the body bag or wrap or if they match the pupae found on the floor or the ground under the corpse. This type of methodology can discriminate between closely related flies and beetles found on corpses (35). This approach has been very helpful in setting the time of death for bodies found less than 1 month after death. After this point, larval insects can be very difficult to identify morphologically when the stages are immature and only fragments of pupae and first-instar larvae are found. An easy and objective method of insect identification is DNA typing; this new approach provides excellent information in a relatively short time (36).

Another relatively new approach involves forensic analysis of DNA recovered from a larva's gut, which can be used to identify the larval food source. This method for associating a maggot with a corpse could be useful, particularly in situations where remains were removed from a suspected crime scene, when an alternative food source is near the scene or the body, or in a chain-of-evidence dispute. However, since maggot gut content analysis represents a new approach, many of the limitations of the technique have not yet been identified. In spite of possible limitations, it appears that third-instar larvae actively feeding on a corpse could be considered an excellent source of human DNA (37, 38).

Insects can also assist in determining the cause of death and can serve as reliable alternative specimens for toxicologic analyses in the absence of tissues and fluids normally used for such purposes. The presence of drugs and/or toxins in decomposing tissues may alter the rate and patterns of development of arthropods feeding on these tissues. Insects can also accumulate heavy metals and toxic compounds, or their by-products, in their tissues (39).

Studies are under way to assess the utility of microsatellite markers to track the movements and sources of corpses via blowflies (40). Cuticular hydrocarbon analysis on first-instar larvae has been applied to three forensically important blowflies, *Lucilia sericata*, *Calliphora vicina*, and *Calliphora vomitoria*, using gas chromatography-mass spectrometry (GC-MS) and principal component analysis. The results show that each species holds a distinct "fingerprint" hydrocarbon profile, allowing for accurate identification to be established in 1-day old larvae. This GC-MS-based technique could enhance the identification process, not only for forensically important species, but also for other entomological samples which are hard to identify using morphological features (41).

Types of Myiasis Categorized According to Affected Tissues

Cutaneous and Mucocutaneous Tissues (Eye, Nose, and Ear). Larval penetration of cutaneous and mucocutaneous tissues causes various degrees of pathologic abnormalities, ranging from an irritating pruritus to invasion of the eyes, brain, nasopharynx, bones, ear canal, vagina, tongue, and open wounds (Fig. 35.15). The only known therapeutic procedure, other than applying local palliatives, is surgical removal and treatment for secondary bacterial or fungal infections (if these occur). Examples of representative fly larvae and their stigmal plates are seen in Table 35.5. *Dermatobia hominis* and *Cordylobia anthropophaga* are the most common causative agents of furuncular myiasis, while lesions from *Cuterebra* sp. and *Wohlfahrtia* sp. are also seen. The stigmal plates or spiracles (respiratory openings) from mature fly larvae are characteristic for each species and can be valuable in identification. The larvae orient themselves so that these spiracles are normally at the surface of the host skin, etc., to allow oxygen exchange by the larvae. The typical furuncular lesion is a papule or nodule with a central area that exudes serosanguinous or purulent fluid. In the central pore, the posterior part of the larva can be seen; the respiratory spiracles (stigmal plates) can also be seen, which can be confused with tiny black eyes. Although a furuncle-like lesion is the most common presentation, variations have been described, including vesicular, bullous, pustular, erosive, resembling a bruise, and ulcerative lesions. Pruritus, pain, and movement sensation are the most reported symptoms.

doi:10.1128/9781555819002.ch35.f15

***Cuterebra* sp.** is an autochthonous facultative cause of cutaneous and ocular myiasis in humans living in North America. Most cases occur in children, involving the face, scalp, neck, shoulders, or chest. Infestations tend to occur in August, September, and October.

Differential diagnoses of furuncular myiasis are furuncle, insect bite, insect prurigo, pyoderma, inflamed cyst, tungiasis, soft tissue infections, cellulitis, periductal mastitis, benign mass, inflammatory carcinoma, herpes simplex, and delusional infestation. Patient history is critical and may reveal relevant travel history or underlying condition(s). Identification of the larva or larvae can be achieved with appropriate specimen collection and fixation. Also, systemic inflammation, peripheral eosinophilia, and elevated IgE may also be confirmed. Although biopsy and routine histology are often performed, the identification of the particular larval species based on larval fragments alone may be somewhat difficult.

Therapy consists of three general techniques: (i) the application of a toxic substance to the larva and egg, (ii) the production of localized hypoxia to force the emergence of the larva, and (iii) the mechanical or surgical removal of the maggots (27). Petrolatum is often used to occlude the breathing mechanism, while polymyxin B is a sterile option. Occlusion may be required for 24 h or more. It is important not to rupture the maggot, thus causing an inflammatory reaction and possible secondary infection.

Intestinal Tissues. Female flies often deposit eggs or larvae on food that is then eaten by humans. Occasionally, some eggs or larvae survive, become temporarily lodged in the intestinal crypts and folds, and partially or completely develop before being passed in the stool (43). Patients may be asymptomatic, or they may present with larvae in the stools, abdominal pain, nausea, vomiting, anal pruritus, or rectal bleeding. The presence of the maggots may cause an inflammation of the intestinal mucosa. Myiasis agents associated with this type of accidental myiasis are *Fannia canicularis*, *Sarcophaga* spp., *Hermetia illucens*, *Muscina stabulans*, *Megaselia scalaris*, *Eristalis tenax*, *Musca domestica*, *Phormia regina*, *Lucilia cuprina*, and *Stomoxys calcitrans*. Around 50 species of fly larvae have been reported, either positively or questionably, from cases of enteric myiasis. These species are principally members of the families *Muscidae*, *Calliphoridae*, and *Sarcophagidae*, which commonly deposit their eggs or larvae on cold meat, cheese, and other food of humans and are thus ingested; the eggs may be swallowed with contaminated food, pass through the intestine unaffected, and be excreted in feces.

Other Sites. There are reports of larvae recovered from urine, the vagina, and the lungs (accidental inhalation of either a gravid female fly or airborne eggs) (9).

Types of Myiasis Categorized According to Tissue Viability

Specific Myiasis. The larvae attack only living tissues of humans and animals, usually cutaneous and subcutaneous areas but also the nose, mouth, sinuses, eyes, ears, anus, and vagina. There are generally six dipterous families represented in this type of infestation (Table 35.4).

Semispecific Myiasis. The larvae breed on the bodies of dead animals and attach to dermal and subdermal areas and cavities. This type of myiasis is represented by four families of dipterous flies (Table 35.4).

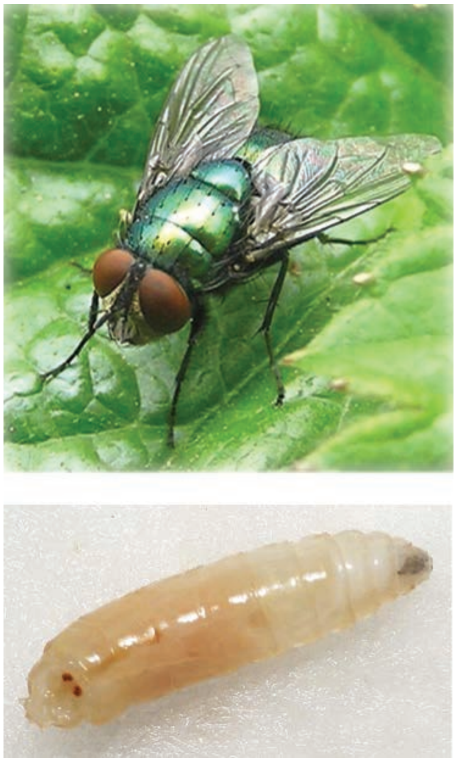
Accidental Myiasis. Infestations are usually accidental and occur infrequently. They are usually in the gastrointestinal tract and are acquired by ingesting food contaminated with larvae. Although the eggs are usually digested or fail to hatch, some may survive, become lodged in the crypts, and develop through part of their life cycle before leaving the body. They may also invade the ears, nose, sinuses, and urinary passages. There are approximately 15 families of flies whose members are implicated in this type of infestation.

Dipterous Flies Involved in Cases of Myiasis

Calliphorid Flies (Blowflies) (*Cochliomyia*, *Phaenicia*, and *Phormia* spp.). Adult blowflies feed on material found in wounds or decaying flesh; females lay their eggs in batches of 200 to 300 in the flesh of dead animals. The eggs usually hatch within 24 h and feed on exudates of wounds or decaying flesh; they penetrate the tissue by using powerful oral hooks, hence the name "screwworm" (Fig. 35.16) (9). Human ophthalmomyiasis has been reported, with one review specifically discussing infection with *Cochliomyia hominivorax* (44). Adult flies have been known to lay eggs on scabs, sores, scratches, pimples, or dried blood; in the healthy mucous membranes of the eyes, nose, mouth, or vagina; and in the umbilicus of neonates. Recent human infestations with *C. hominivorax* include the axilla, nose, palate, and mastoid cells. Blowflies often appear shiny or coppery green to shiny black.

An unusual case of *Phormia regina* myiasis of the scalp was reported in 1988. *P. regina*, the black blowfly, causes

Figure 35.16 *Lucilia* (*Phaenicia*) sp. (blowfly). (Upper) Adult fly (courtesy of Derrick Ditchburn, http://www.dereila.ca/whispers/flies3.html). (Lower) Larva prior to pupation. doi:10.1128/9781555819002.ch35.f16

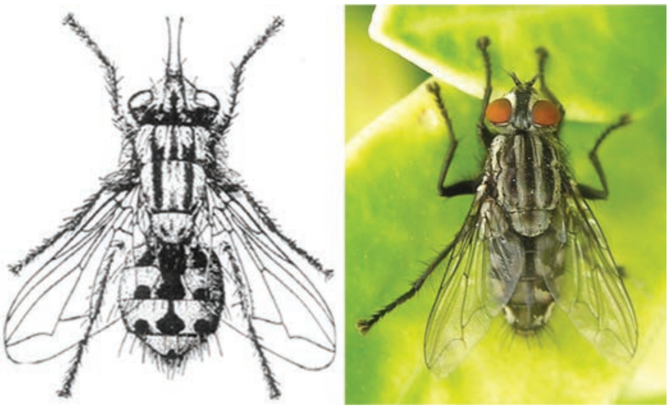


facultative myiasis, usually invading wounds, benign and malignant ulcers, and other diseased tissue; rarely are normal tissues involved. However, in this case, there were no recognizable associated infected wounds or tumor. The patient was a 64-year-old homeless woman who had numerous scratches on her scalp. There is speculation that infection started with the repetitive scratching and that the open suppurative scalp wounds, which were never washed, were likely sites for egg deposition. *P. regina* is very common throughout the United States, especially during April to September (45).

Flesh Flies (*Sarcophaga*, *Wohlfahrtia*, and *Parasarcophaga* spp.). The adult flies feed on feces or decaying meat or fish (9); females deposit 40 to 80 first-stage larvae. The larvae penetrate the tissue, thus causing problems depending on the body site (Fig. 35.17).

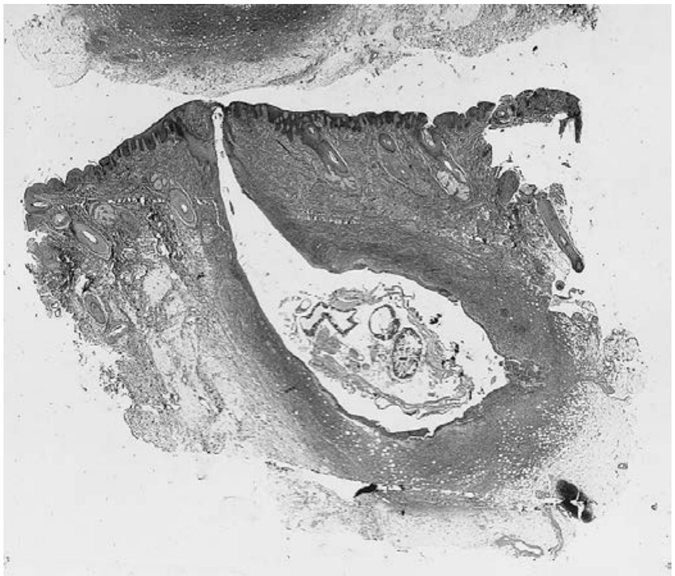
Medically important genera of flesh flies include *Wohlfahrtia* and *Parasarcophaga*. *Wohlfartia magnifica* never develops in carrion, but is found in wounds and natural orifices of warm-blooded animals, including humans. *Wohlfartia vigil* occurs in northern North America, and the larvae are not as invasive, usually being limited to dermal tissues and causing a boil-like lesion. The first reported case of human aural myiasis caused by the flesh fly *Parasarcophaga crassipalpis* was reported in 1987. The patient was a 16-year-old, mentally disabled, nonresponsive Caucasian boy at a public institution in Adelaide, South Australia. Some blood was noticed in the left external ear canal, and 2 weeks later, dark blood was seen discharging from the ear. The physician detected movement in the ear, and that evening a single maggot emerged from the ear. No other maggots were found, and there was no tissue damage in the external ear canal.

Figure 35.17 Flesh fly (*Sarcophagidae*), causes myiasis in humans. (Left, adapted from James MT, U.S. Department of Agriculture Miscellaneous Publication 631, 1947; right, color image courtesy of Derrick Ditchburn, http://www.dereila.ca/whispers/flies3.html.) doi:10.1128/9781555819002.ch35.f17



Botflies (*Dermatobia hominis*, *Gastrophilus* spp., *Hypoderma* spp., *Cuterebra* spp., and *Oestrus ovis*) (Cutaneous, Ophthalmic, Nasal, and Aural Myiasis). The adult female *Dermatobia hominis* fly never feeds but uses food stored up during the larval stage for egg production. Once the eggs are developed, the female fly captures a mosquito or other blood-sucking arthropod and glues the eggs to the abdomen of the arthropod. When the arthropod lands on a warm-blooded host, the young larvae emerge from the egg membranes and, within less than an hour, invade the skin. Lesions commonly occur on the unprotected skin; the tunnel produced is generally perpendicular to the surface and is occupied by a single larva. Eventually, local tissue destruction and accumulation of toxic waste produce throbbing pain and intense itching. The lesion may resemble a bacterial infection with seropurulent fluid (Fig. 35.18–35.21). *D. hominis* is not found within the United States; however, cases are seen in travelers returning from areas of endemic infection that include parts of Mexico and Central and South America.

Figure 35.18 Myiasis. Nodule from the pubis of a 24-year-old woman. She was bitten while in a banana grove in Colombia 2 weeks before this nodule was removed. The fly larva is coiled in a cyst that communicates with the surface. The cyst and tract are lined in part by squamous epithelium. This lesion is characteristic of the "warble" or boil of *Dermatobia hominis*, although the species could not be determined from the section studies. (Armed Forces Institute of Pathology photograph.) doi:10.1128/9781555819002.ch35.f18



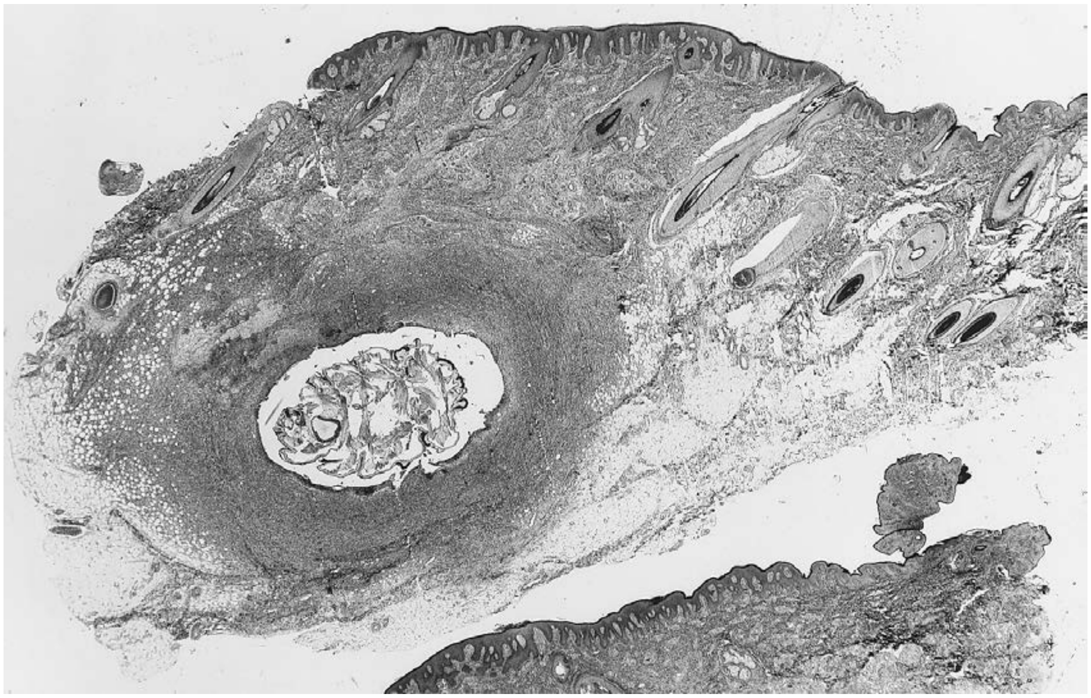


Figure 35.19 Myiasis. Higher magnification of the lesion in Fig. 35.18. The larva is surrounded by an intense inflammatory cell infiltrate composed of neutrophils, lymphocytes, plasma cells, and eosinophils. Magnification, ×9.7. Figure 35.20 Myiasis. A portion of the spiracular system of the larva shown in Fig. 35.18 and 35.19. Note the distinct tracheal rings. Magnification, ×440. (Armed Forces Institute of Pathology photograph.) doi:10.1128/9781555819002.ch35.f20

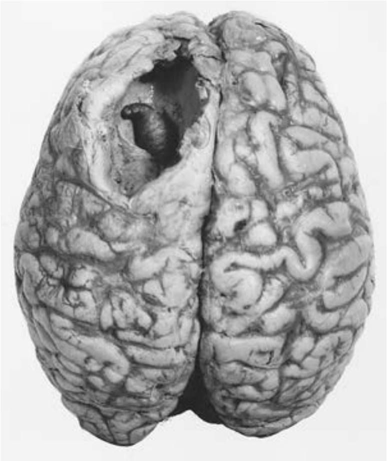

Figure 35.21 Myiasis. Brain of a child in Panama who died of malaria. There were several warbles on the scalp. The larva in the cavity entered through a 4-mm hole that it had bored through the anterior fontanelle. The shape and spines of the larva are consistent with *Dermatobia hominis*. (Armed Forces Institute of Pathology photograph.) doi:10.1128/9781555819002.ch35.f21

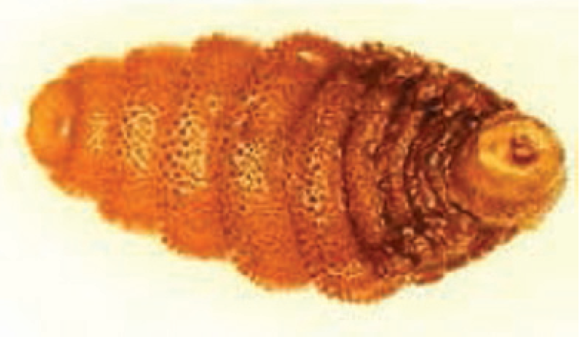
Although human infestation with *Gastrophilus* larvae is uncommon, the lesion is usually cutaneous. The larvae may advance in the tunnel, with the lesion resembling that of *Ancylostoma braziliense* (cutaneous larva migrans). Ophthalmomyiasis due to *Gastrophilus intestinalis* has also been reported.

Flies of the genus *Hypoderma* most commonly cause dermal myiasis in humans in the United States. The lesions are less serpiginous than those caused by *Gastrophilus* spp., particularly since the larvae bore more deeply into the subcutaneous tissues and produce a more inflamed lesion. However, since the larvae do migrate, they can appear many centimeters from the original site in a month's time. It is important to try to remove the larva before it dies and thus causes a more severe problem due to infection and pus formation.

The genus *Cuterebra* contains more than 20 species of flies native to North America, and the larvae occur as dermal parasites of rodent and rabbit hosts; human cases tend to be somewhat rare. A case of cutaneous myiasis of the eyelid as a result of a *Cuterebra* larva has been reported. The patient was a 28-year-old man with a 3-week history of a swollen, tender nodule on his right upper eyelid. Apparently, 2 weeks before symptoms appeared, he was bitten on his shoulder by an insect. Redness and swelling developed and spread into the neck, face, and right upper eyelid during the following week. The patient was treated for periorbital cellulitis and a secondary *Pseudomonas* infection in the lesion, with no improvement. Two days after the lesion was finally incised, an oval larva emerged and was identified as a second-stage *Cuterebra* larva. Another patient (Fig. 35.22) had a pruritic "mosquito bite" on the chest, which became inflamed and enlarged to approximately 4 cm. A "head" developed, from which the patient expressed this larva. Subsequently, the larva was identified as *Cuterebra* sp.

Figure 35.22 Fly larva removed from a man living in Lynchburg, VA. The patient had a pruritic "mosquito bite" on the chest, which became red and then enlarged to about 4 cm. A "head" developed, from which the patient expressed this larva. The larva was identified as *Cuterebra* sp. Magnification, ×22. (Armed Forces Institute of Pathology photograph.)
doi:10.1128/9781555819002.ch35.f22



Gravid females of *Oestrus ovis* deposit their first-stage larvae onto the conjunctiva, the outer nares, or the lips or into the buccal cavity. These larvae have large oral hooks and spines that assist their penetration through the mucous membranes. The larvae may burrow into the eyelid, conjunctival sac, or lachrymal duct. Human ophthalmomyiasis is common in the former USSR, northern Africa, and Israel; however, it is rare in Western Europe and the United States. Invasion of the nasal sinuses may result in congestion accompanied by pruritus and frontal headache. Generally, with the exception of the eye, the larvae spontaneously leave the tissues. In cases in which the eye is involved, patients may present with ocular symptoms of foreign-body sensation, irritation, redness, and photophobia. Topical antibiotics and steroid eye drops can be used. Patients may also develop nasal symptoms such as sneezing, nasal discharge, and epistaxis. Larvae can be removed from the conjunctival sac under local anesthetic with no difficulty. Otolaryngology follow-up may demonstrate nasal myiasis as well. Some patients have been treated with ivermectin (46).

Maggot Therapy. Maggot therapy involves induced myiasis performed in a controlled environment by experienced medical personnel. The safety and success of the treatment depend on the selection of an appropriate myiasis species that feeds almost exclusively on necrotic tissue. *Lucilia sericata* is considered the most suitable species for maggot therapy. The larvae are prepared and maintained sterile prior to clinical use (Fig. 35.16).

Maggot therapy has three basic effects on a wound: debridement, disinfection, and enhanced healing. Debridement is the removal of cellular debris and nonviable necrotic tissue from the wound bed. The removal of necrotic tissue, which acts as a microbial substrate, may also reduce the risk of infection. Maggots debride wounds quickly and effectively, without damage to viable tissue. Maggots are photophobic and will naturally move into the deep crevices that may be beyond the reach of a surgeon's scalpel. Reports have confirmed the benefits of maggot debridement therapy in many wound situations (47).

Order Hemiptera (True Bugs)

Bedbugs (*Cimex lectularius*, *Cimex hemipterus*)

Cimex lectularius has a wide distribution, while *C. hemipterus* is primarily tropical. Bedbugs measure about 5 mm long by 3 mm wide, are mahogany brown, and have only vestigial wings (Fig. 35.23). The adult bugs may resemble unengorged ticks or very small cockroaches. Although they

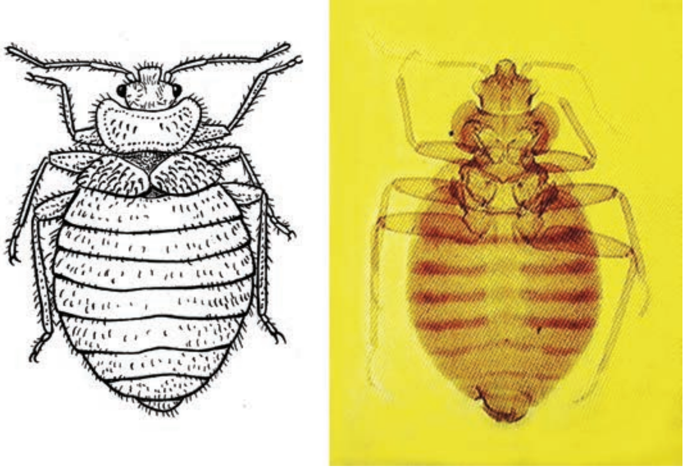


Figure 35.23 Bedbug (*Cimex* sp.). (Left) Adult, 5 mm (illustration by Sharon Belkin, based on an illustration from Najarian HH, *Textbook of Medical Parasitology*, The Williams & Wilkins Co., Baltimore, MD, 1967). (Right) Color image.

doi:10.1128/9781555819002.ch35.f23

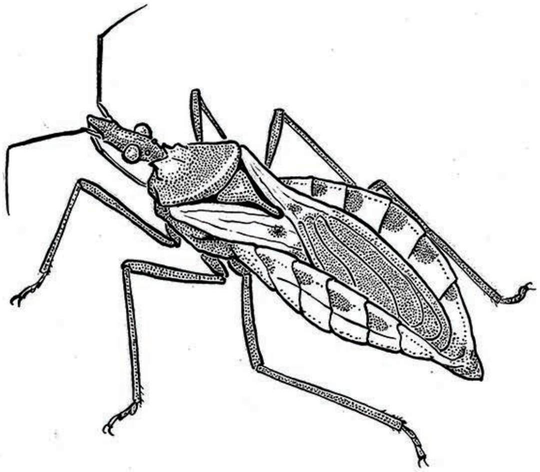
can mechanically transmit pathogenic microorganisms, there is no conclusive evidence that they are natural biological vectors for the transmission of organisms causing diseases. Medical problems associated with these bugs include itching and inflammation caused by their bites. Bedbugs are nocturnal and reach their peak activity before dawn; they tend to hide in cracks during the day. They respond to warmth and carbon dioxide in their search for hosts and will respond to a body that is 2°C or more above ambient temperature. They produce an aggregation pheromone that brings them together. Both sexes of nymphs and adults take blood meals, and blood is the sole food of these bugs. The nocturnal biting of bedbugs can be debilitating to humans, whose sleep is interrupted every night. The presence of the bugs can be suspected by finding their specks of feces and their odor. Bedbugs are very common in developing countries and are becoming more common even in the United States. Travelers may import bugs in their suitcases or belongings, and the bugs then “make themselves at home” in cracks and crevices, behind baseboards, and under mattresses.

Triatomid, Reduviid, Kissing, or Conenose Bugs (Chagas’ Disease)

Triatomid bugs have well-developed wings, are larger than bedbugs, and have a cone-shaped head (Fig. 35.24). These bugs are usually brown or black with orange and black markings on the abdomen where it extends beyond the folded wings. Most species are hematophagous, feeding primarily on mammalian or avian blood. The infective forms of *Trypanosoma cruzi* (Chagas’ disease) are found in the bug’s feces (48). In areas where the infection is more prevalent, the bugs tend to defecate very soon after taking a blood meal. Since the bug’s saliva contains an irritant, the person tends to scratch, thus scratching in the infective forms from the bug feces. The time of the blood meal and the number of feeds during engorgement in relation to defecation are important epidemiologically and are directly related to infection potential.

The earlier a bug defecates during or after feeding, the more likely it is to be an efficient vector. Most triatomid bugs are nocturnal and feed on sleeping inhabitants of the house. They are attracted to the host by warmth, carbon dioxide, and odor. The bites are relatively painless, hence the name “kissing bug.” Obviously it would not be advantageous for the person to wake up before the bugs complete their blood meal and subsequently defecate. However, some individuals have an allergic reaction to the bite approximately 24 to 48 h later; in some cases this is serious. Edema of the eyelids and conjunctivitis may occur (Romaña’s sign) (Fig. 35.25). The edema does not pit on pressure, and the skin is dry. Although Romaña’s sign is thought to be almost pathognomonic for early Chagas’ disease, in an analysis of 300 patients with early disease, unilateral periorbital edema was found in only 48.7%. Currently, it is estimated that 16 million to 18 million people are infected with *T. cruzi* and 90 million to 100 million are at risk. Although most cases occur in Mexico and Central and South America, indigenous cases have been reported from Texas, Tennessee, and California. Serologic evidence places *T. cruzi* as far north as Oklahoma. Five species of kissing bug are found within different parts of the United States: *Triatoma protracta*, *T. gerstaeckeri*, *T. sanguisuga*, *T. rubida*, and *T. rubrofasciata*.

In addition to an irritant, the bug saliva contains an anticoagulant, so that the blood remains unclotted when stored within the bug. This ensures that the blood remains fluid for easier passage into the digestive system of the midgut. In areas of endemic infection, the number of bugs may vary tremendously in houses that harbor the triatomids. When a heavily infested house in Venezuela was torn down, nearly 8,000 triatomid bugs were recovered. It was calculated that in that house the feeding rate was 58 bugs per person per day. The loss of blood per person per month



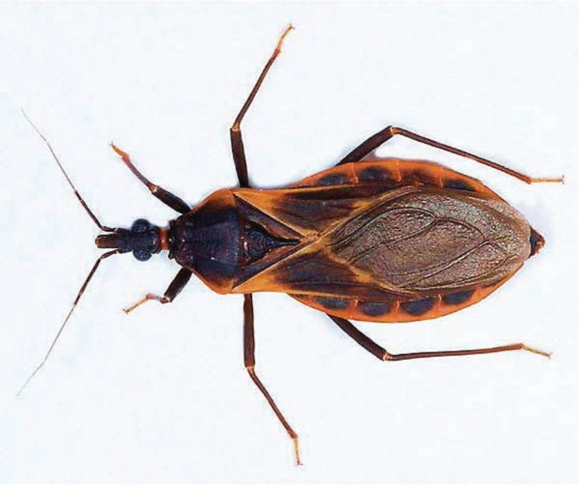


Figure 35.24 Triatomid bug (*Triatoma* sp.). (Upper) Adult bug, 25 mm (illustration by Sharon Belkin). (Lower) Color image of *Triatoma rubida*, the most abundant triatomine species in southern Arizona (courtesy of the CDC Public Health Image Library, photograph by C. Hedgcock). doi:10.1128/9781555819002.ch35.f24

can range from 0.7 to 40 ml; however, in that particular house, it exceeded 100 ml (4).

Most reduviids kill other insects; the name "assassin bugs" is used as a general term. However, bugs associated with the transmission of *T. cruzi* are referred to as kissing bugs. While assassin bugs may bite humans, producing painful lesions, they are not associated with parasite transmission. Often the general names are used interchangeably, thus confusing the issue of actual parasite transmission.

Order Coleoptera (Beetles)

Epicauta. The majority of beetles, representing over 40% of all insects, are not harmful to humans. In some cases, the adult beetles contain vesicating substances such as pederin (paederin) (an amide within body fluids) and cantharidin (a volatile terpene found in the hemolymph) (*Epicauta* spp., *Paederus* spp.). Cantharidin, a bicyclic terpenoid, has an inhibitory effect on protein phosphatase 1 (PP1) and protein phosphatase 2A (PP2A). It is stored in the hemolymph, genitalia, and other tissues of the blister beetles, such as those in the genus *Epicauta* (family *Meloidae*) (Fig. 35.26). When these beetles are accidentally crushed against the skin, serious blistering may occur (Fig. 35.26 and 35.27). This type of dermatitis occurs more commonly over the uncovered parts of the body, and the majority of the lesions tend to be on the neck and face. Most of these beetles are seasonal and may be found in large numbers in some fields at certain times of the year. Cantharidin, a natural toxin from blister beetles, used as a medicinal agent since antiquity, has been described to modulate the hepatic leukemia factor competitor NFIL3 and is under clinical evaluation as an antitumor and antimetastatic agent (50).

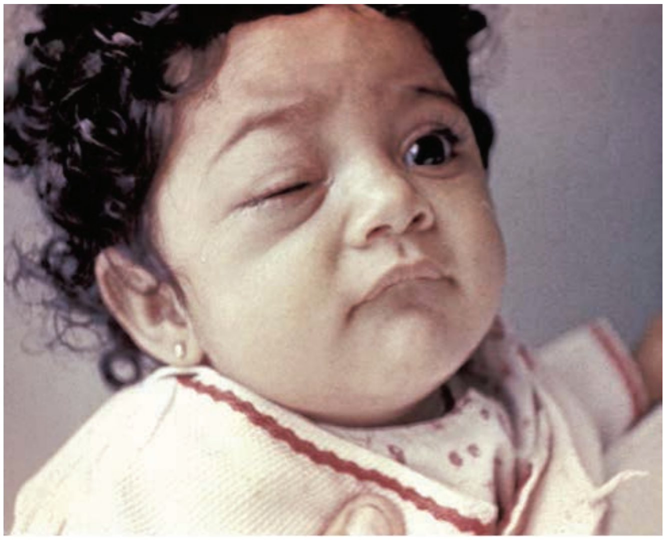

Figure 35.25 Romaña's sign; the assumption is that this is the bite site of the vector, the triatomid bug; unilateral conjunctivitis, palpebral and periorbital edema (courtesy of the Armed Forces Institute of Pathology). doi:10.1128/9781555819002.ch35.f25

Paederus. Beetles in the genus *Paederus* are attracted to the light. They do not bite or sting, but accidental brushing against the beetle or crushing it over the skin provokes the release of its coelomic fluid, which contains pederin, a strong blistering amide that produces a painful blister (Fig. 35.27). There is usually no immediate response to the fluids, but in 24 to 48 h a wheal appears and is followed by blisters. The erythema may last for several months. Ocular and genital involvement is relatively common; it occurs secondary to transfer of the toxic chemical from elsewhere on the skin by fingers. Ocular involvement usually presents with unilateral periorbital dermatitis, or kera-

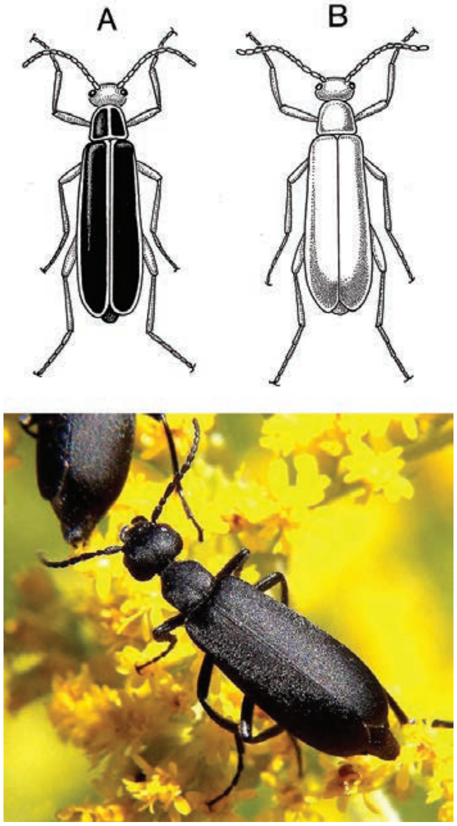

Figure 35.26 Blister beetles. (Upper) (A) Margined (*Epicauta pestifera*); (B) ash gray (*Epicauta fabricii*) (illustration by Sharon Belkin). (Lower) *Epicauta pennsylvanica*, black blister beetle (courtesy of Bruce Marlin, www.cirrusimage.com/beetles.htm). doi:10.1128/9781555819002.ch35.f26

toconjunctivitis, which has been named the Nairobi eye and can cause temporary blindness.

Adult *Paederus* beetles are usually 7 to 10 mm long and 0.5 to 1 mm wide, about one and a half times the size of a mosquito. The head, lower abdomen, and elytra (structure covering the wings) are black and the thorax and upper abdomen are red. It is important to note that *Paederus* beetles are not "blister beetles," which are of the family *Meloidae* (see *Epicauta* above). Blister beetles, which also are widely distributed, release a defensive compound when threatened. The chemical released, cantharidin, a bicyclic terpenoid, is quite different from pederin, an amide.

The manufacture of pederin is largely confined to the female insect. The toxin pederin is the most complex nonproteinaceous insect secretion known and has been used in Chinese medicine for over 1,000 years. Recently, it has been demonstrated that the production of pederin relies on the activities of an endosymbiont (*Pseudomonas* species) within the beetle (51).

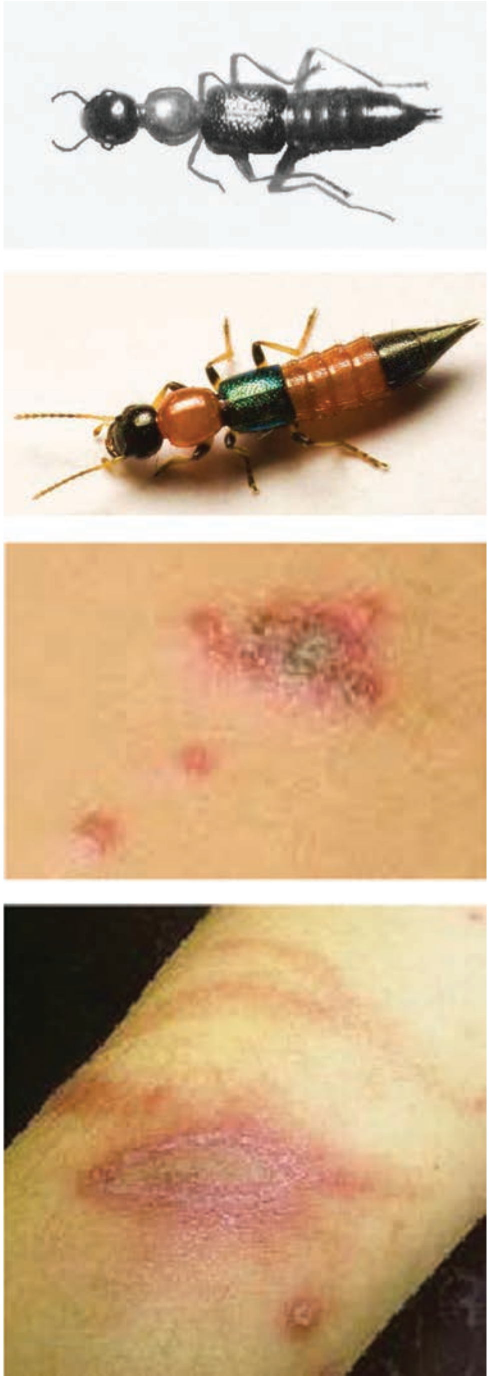

Figure 35.27 (Top) *Paederus laetus*, a beetle of Central America which elaborates a vesiculating toxin. (Row 2) Color image of *Paederus* sp.; magnification, ×4. (Row 3) Contact dermatitis from staphylinid beetle, *Paederus* sp., on the body of a man in Ethiopia. (Bottom) Dermatitis after crushing a beetle on the skin. (Armed Forces Institute of Pathology photographs.) doi:10.1128/9781555819002.ch35.f27

Preventing human/beetle contact is the primary method of avoiding *Paederus* dermatitis. Learning to recognize *Paederus* beetles and avoiding handling or crushing these insects will help decrease these eruptions. If a beetle lands on the skin, it should be blown off or encouraged to walk onto a piece of paper and then removed. The area in contact should be immediately washed with soap and water, and any clothes in contact with the beetle should be washed as well.

***Lytta*.** Another important beetle in the family *Meloidae* is in the genus *Lytta*, which contains the infamous "Spanish fly" from which the well-known aphrodisiac powder is obtained. Cantharidin ("Spanish fly") is a chemical with vesicant properties derived from blister beetles, which have been used for millennia as a sexual stimulant. Its mode of action is by inhibition of phosphodiesterase and protein phosphatase activity and stimulation of beta-receptors, inducing vascular congestion and inflammation. Morbidity from its abuse is significant. The ingestion of live beetles (*Palembus dermestoides*) in Southeast Asia and triatomids in Mexico may have a basis similar to cantharidin (52).

Order Siphonaptera (Fleas) (*Ctenocephalides* spp., *Xenopsylla cheopis*, *Pulex irritans* [Human Flea], *Tunga penetrans*, *Nosopsyllus fasciatus*, *Echidnophaga gallinacea*, and "Sand Fleas")

Fleas are wingless ectoparasites of mammals and birds. While lice are usually host specific, fleas parasitize a number of hosts. It is this ability to move from one host to another that facilitates the transfer of disease from animals, primarily rats, to humans. Fleas are laterally flattened and have no wings. The legs are long and muscular, which allows them to jump (Fig. 35.28). They have piercing-sucking mouthparts, with which both sexes of adults obtain blood meals. They are hosts and transmitters of several pathogenic organisms including the agents of plague and murine typhus and *Dipylidium caninum*, the dog tapeworm. Also, their bite or presence in the skin causes dermatitis or ulcerations.

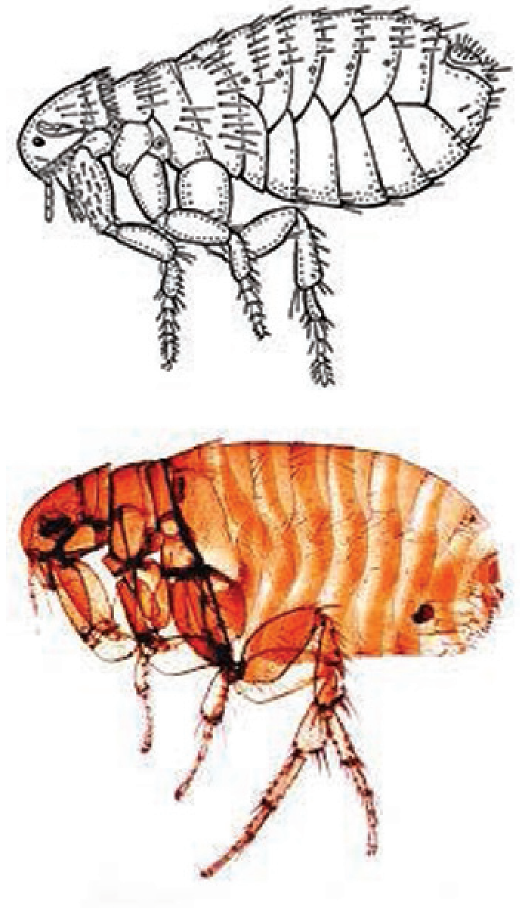

Figure 35.28 Flea. (Upper) Adult flea, 1.5 mm (illustration by Sharon Belkin). (Lower) Color image (from *A Pictorial Presentation of Parasites*: a cooperative collection prepared and/or edited by H. Zaiman). doi:10.1128/9781555819002.ch35.f28

Medically important fleas include *Tunga penetrans* (Fig. 35.29 and 35.30). The adult female *Tunga penetrans* burrows head first into human skin until its head lies within the dermis. The rest of the body is enclosed by the epidermis. A small hole in the keratin remains open, which allows the flea to breathe and discharge feces and eggs to the outside. The penetration of the flea produces no symptoms; however, the expanding flea creates a painful erythematous nodule. Unfortunately, this condition can lead to ulceration, sepsis, tetanus, or gangrene. The fleas can be found on any part of the body, but most often on the feet. Since this flea is a poor jumper, its height range is limited to a few centimeters above the ground. Nodules under a toenail or in pressure-bearing areas of the foot can be extremely painful. The burrowing flea usually appears as a small black spot in the skin. In 95% of cases the injury is in the feet, with a predilection for the plantar region, ankle, and interdigital periungual surfaces. In the remaining 5 to 10% of cases, *T. penetrans* affects other body sites such as hands, elbows, thighs, buttocks, and eyelids. Tungiasis can be misdiagnosed as creeping eruption, dracunculiasis, tick bite, scabies, or myiasis. Flea removal by dissection is the best treatment approach; however, the procedure must be handled carefully. If the flea ruptures, a painful inflammatory reaction may occur, requiring additional intervention. Thiabendazole is usually effective, and niridazole and ivermectin have also been used. Although wearing closed shoes is recommended, this is not always possible, depending on

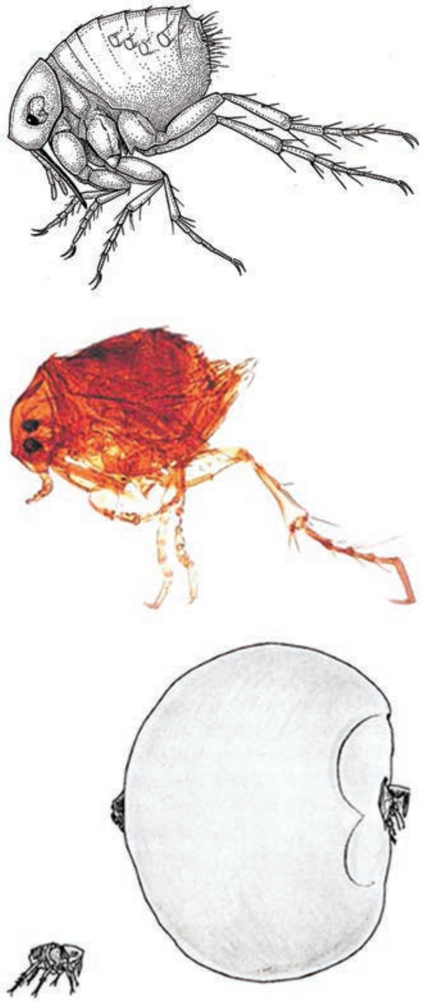

Figure 35.29 Flea (*Tunga penetrans*, chigoe flea). (Top) Adult flea, 1.5 mm (illustration by Sharon Belkin). (Middle) Color image. (Bottom) Diagram of female flea, non-gravid (left) and gravid/full of eggs (right). (Middle and bottom, Armed Forces Institute of Pathology photographs.)
doi:10.1128/9781555819002.ch35.f29

the geographic area. Tungiasis in travelers usually is a benign self-limiting skin disease, whereas inhabitants of areas of endemicity suffer from heavy infestations and severe, frequently debilitating and incapacitating morbidity (53).

Other medically important fleas include *Pulex irritans* (the human flea), *Ctenocephalides canis* (the dog flea), *Ctenocephalides felis* (the cat flea), and *Xenopsylla cheopis* (the Oriental rat flea). Generally the flea bites begin with a wheal around each site within about 5 to 30 min. Itching is common, with the production of an indurated papule within about 12 to 24 h. In people who are sensitive to the bites, a delayed reaction appears in about 12 to 24 h and lasts for a week or longer. The intense itching is often sufficient cause for the patient to consult a physician.

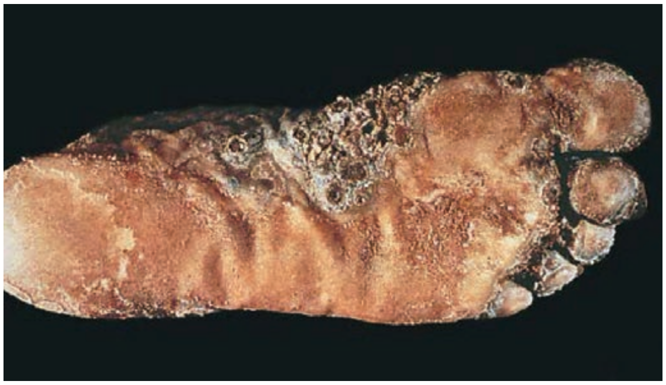

Figure 35.30 Tungiasis. Multiple and irregularly confluent tunga craters on the foot of an African patient. The nonpressure areas (arch and between the toes) are the most severely involved. The weight-bearing portion of the sole tends to be spared. This patient died of tetanus. Note the lesions are healing and crusted. (Armed Forces Institute of Pathology photograph.)
doi:10.1128/9781555819002.ch35.f30

Cat and dog fleas, *C. felis* and *C. canis*, are major domestic pests in many parts of the world, including North America and Australia; however, the cat flea is most often found within the United States. Both types of flea can feed on either animal. Dogs tend to be more allergic to flea saliva than are cats, but both can have severe reactions to heavy infestation. Cats can remove about 50% of their fleas in a single week, but insecticide dust, spray, shampoo, or other options may be required for removal of all fleas. Flea larvae are very sensitive to drying, and outdoor environments do not generally support survival, which requires a relative humidity of >50%. In the transmission of *D. caninum*, the tapeworm eggs are ingested by the larval stages of the dog, cat, or human flea, where they develop into cysticercoid larvae. When these fleas are then ingested by the definitive host (dogs, cats, or humans), the adult worm develops within 3 to 4 weeks. Most of these infections have been found in children.

Although *Echidnophaga gallinacea* (the sticktight flea) is associated with poultry, it may also feed on humans. Chickens are commonly seen with flea “patches” around the comb, wattles, or even the eyes.

“Sand fleas” is a general term that is used for a number of arthropods, only some of which are actually fleas. In the northern United States, sand fleas are usually dog or cat fleas associated with stray animals. In the western United States, cat or human fleas associated with a number of different animals are called sand fleas. Along the coastal areas, small amphipod crustaceans found in seaweed are also called sand fleas.

Order Anoplura (Sucking Lice)

The order Anoplura contains the blood-sucking lice (*Pediculus* and *Phthirus* spp.), which have legs with claws adapted for clinging to hairs or fibers. There are three nymphal stages prior to the adult, and all stages feed on blood. In general, the biting lice respond to warmth and smell, avoid high humidity, and are negatively phototactic (i.e., they move toward dark objects). There are several types of human lice: the head louse, the body louse, and the pubic or "crab" louse (Fig. 35.31 and 35.32). The head and pubic lice deposit and cement eggs onto the hair shaft (Fig. 35.33), whereas the body louse deposits eggs on clothing, particularly in the seams. Although they do not specifically transmit any parasites, they do transmit epidemic typhus and louse-borne relapsing fever. Prevention involves both treatment of individuals and mass control, both of which can be difficult in situations such as jails, refugee camps, army barracks, and schools (9).

Body Lice

In a stable population of the body louse, *Pediculus humanus*, more than two-thirds of the lice are present as eggs, about one-fourth are present as nymphs, and only 6 to 7% are present as adults. The adults measure 2 to 3 mm for the male and 2.4 to 3.6 mm for the female. Body lice can cause severe skin irritation; there may be swelling and the development of papules at the bite sites, as well as mild or severe itching. Some individuals may become sensitized to antigens introduced during louse feeding, and they can experience generalized allergic reactions. Removal of skin during itching can also lead to secondary infection. The lice tend to attach to cloth fibers along the seams inside of underwear or other places where clothes touch the body; they tend to prefer wool clothing. *P. humanus* can be removed from clothes by heating the clothes to >60°C for 15 min; this could be accomplished by placing clothes in the clothes drier for about 20 to 30 min.

Figure 35.31 Body louse (*Pediculus* sp.), 1.5 mm (left, illustration by Sharon Belkin; right, courtesy of the CDC Public Health Image Library). doi:10.1128/9781555819002.ch35.f31

(Color images courtesy of the CDC Public Health Image Library.) doi:10.1128/9781555819002.ch35.f32

Lice infestation dates from approximately 25 million years ago. Clothing lice affect predominantly homeless and

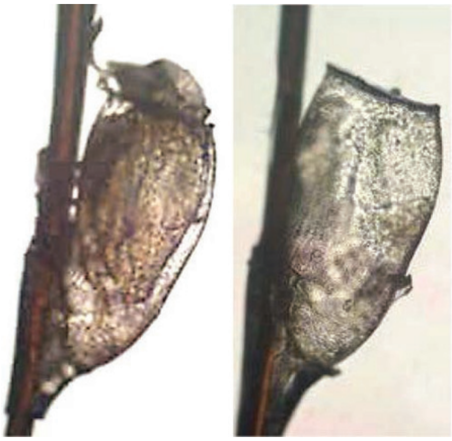

Figure 35.33 Head louse, *Pediculus humanus capitus*. (Left) Egg (nit) on hair shaft with a first-instar nymph starting to hatch out. (Right) Empty shell of the nit from the left image, the nymph having left. (Courtesy of the CDC Public Health Image Library.) doi:10.1128/9781555819002.ch35.f33

refugee-camp populations and are less prevalent than head lice but far more serious because they transmit at least three deadly bacterial pathogens, those responsible for epidemic typhus (*Rickettsia prowazekii*), trench fever (*Bartonella quintana*), and relapsing fever (*Borrelia recurrentis*). However, head lice have been found to carry *Bartonella quintana* in Nepal, the United States, and Ethiopia (54).

Head Lice

Infestation with *Pediculus humanus capitis* or head lice is a common health problem. It most commonly involves children between 5 and 13 years old and is one of the most common parasitic infections of children. Despite worldwide distribution, this infestation more commonly occurs in crowded living conditions and developing countries. Although most infestations are asymptomatic, pediculosis capitis may result in considerable discomfort, parental anxiety, and embarrassment to the child; unnecessary absence from school and work also has adverse effects on the schoolchildren's academic performance. It is more common in longer hair length, and head-to-head contact is by far the most common route of lice. Head lice may also be transmitted by inanimate objects such as clothes, hats, scarves, combs, towels, bedding, hair brushes, and upholstered furniture or carpets. Hundreds of millions of head louse infestations affect children every year, and this number is on the rise, in part because of increased resistance to insecticides.

Head lice (*P. humanus capitis*) live on the skin among the hairs on the patient's head. Their life span is about 1 month if they are not removed from the body, and the life cycle from egg to adult takes about 3 weeks. Washing the hair reduces the number of nymphs and adult *P. capitis*, and combing with a finely toothed comb removes most of the eggs; combing should be done when the hair is damp. During the washing process, the lice feces are also removed; they can also serve as an irritant during the infestation. It is important to remember that if one person in the family has head lice, the entire family should be treated, since others in the family may be infested but may not be aware of it. Most of the products designed for louse removal are effective, provided that directions are followed. In refugee camp situations where body lice can multiply and spread quickly and easily, DDT dust can be applied to clothing; however, resistance to DDT has arisen, and other insecticides may be required for control.

It is important to remember that hair casts (pseudonits), due to dandruff, can be easily confused with head lice. Examination of the hair shafts with a microscope can help distinguish between the vital nits of an active infestation and hatched empty eggs, as well as actual nit eggs versus pseudonits.

Pubic or Crab Lice

The two distinct species of *Phthirus pubis* occur on separate hosts, the human and the gorilla. Adult pubic lice are dark gray to brown and have a typical "crab" shape. This louse has a smaller body of 1.2 by 0.8 mm, may be lighter in color, and is not as mobile and therefore is harder to see with the naked eye. *P. pubis* occurs on the hair in the pubic and perianal areas of the human body and occasionally the axillae, eyebrows, and beard. The incidence of this infestation has been on the increase, and some think that it may be the most contagious sexually transmitted disease (Fig. 35.32). However, this infection is often found in association with other venereal diseases, including gonorrhea and trichomoniasis.

Transmission can occur by sleeping in the same bed as another infested individual. In patients with an infestation of *P. pubis*, there tend to be blue or slate-gray macules on the skin (maculae caeruleae); these are thought to be either altered patient blood pigments or possibly substances occurring in the salivary glands of the lice. Once these lice have left the host, their survival time is relatively short, with death occurring in less than 48 h at 15°C. If infestation occurs on the eyelids, there may be inflammation of the eyelids. These lice live only on humans, require human blood for survival, and do not infest rooms, carpets, beds, or pets. Because the lice tend to die fairly quickly once they are off the host, it is not necessary to use insecticidal sprays or fogs in the home, work, or school environment.

Phthiriasis palpebrarum is an ectoparasitosis in which *P. pubis* infests the eyelashes. It is rare and it can easily be misdiagnosed as blepharitis. Pediatric phthiriasis palpebrarum can represent child abuse, and the origins of this infection need to be carefully determined. A thorough history can provide information to assess whether further action is needed and, if in doubt, social services should be contacted to ensure child safety. This condition is now grouped under sexually transmitted diseases. It provides a useful tool in forensic medicine in cases of rape and sexual abuse; the host DNA can be identified from the blood meal of the louse via PCR and gene sequencing. This lice infestation is commonly misdiagnosed as bacterial, viral, or allergic conjunctivitis or seborrheic dermatitis. Proper history taking and careful examination are a must for correct diagnosis and appropriate treatment.

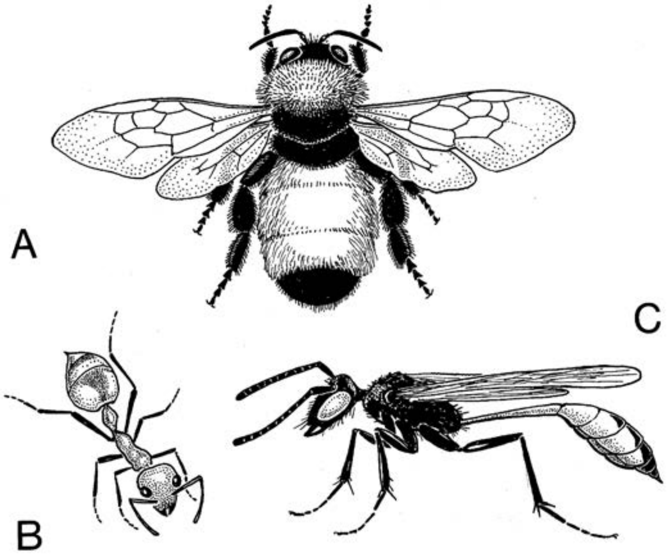
Order Mallophaga (Biting and Chewing Lice)

Biting lice are morphologically similar to other lice and are not very important in human medicine, although they serve as the intermediate host for the dog tapeworm, *Dipylidium caninum*. Infestations are more common in puppies, very old dogs, or those that are sick or debilitated. None of these lice live on humans but are primarily ectoparasites of birds and mammals, feeding on feathers, hairs, and epidermal scales (9).

Order Hymenoptera (Bees, Wasps, and Ants)

The order Hymenoptera contains insects with two pairs of membranous wings, reduced veins in the wings, and hind wings smaller than the fore pair and interlocked with the latter by means of hooklets (Fig. 35.34). There are more than 100,000 described species. Many members of species within this order live together in great structured societies, and reproduction is performed either by many of the female members or, in some cases, by a single individual known as the queen. Members of the group or colony tend to attack intruders.

Figure 35.34 (A) Bee; (B) fire ant; (C) wasp. (Illustration by Sharon Belkin.) doi:10.1128/9781555819002.ch35.f34



Bees

Although stings of members of this order normally cause only temporary pain and swelling, anaphylaxis may occur in patients who are sensitized. Within the United States, approximately 50 to 100 individuals die each year from severe anaphylactic reactions to bee and wasp stings (55). Honeybees are not necessarily aggressive, but they tend to be everywhere outdoors during the summer months. During the stinging process, pheromones are released that cause other bees in the vicinity to attack the victim. When a person has been stung, the stinger should be removed, the site should be disinfected, and ice packs should be applied to slow the spread of venom. The stinger can be removed by scraping with a knife or fingernail to prevent further venom from being injected. If the person experiences a severe local reaction, oral antihistamines and topical application of corticosteroids can be used. Systemic allergic reactions can be a life-threatening emergency requiring immediate medical help.

In 1956, Africanized bees began to spread to the American continent from southern Brazil, where original African bees mated with European bees. In 1990, these Africanized bees reached the United States and were found in Texas. They are now found in other states and will probably reach the Canadian border in the future. The spread of the Africanized honeybee to Brazil and then to other areas of South and Central America and the southern United States has been accompanied by extensive publicity. These bees can be easily irritated and provoked to protect the hive, resulting in hundreds of stings, severe reactions, and death. Although the public has received information regarding these bees, the “killer” bees are difficult to differentiate from normal honeybees, particularly visually.

In comparison to the European honeybee, the Africanized bees tend to attack more readily, remain angry for extended periods, and display massive group stinging behavior in defense of the colony and territory. Although their stings are no more toxic than those of domestic bees, death can result from the cumulative effects of numerous stings, numbering from 400 to 1,000 stings, or from anaphylactic shock. It is very likely that we will continue to see more problems and possible deaths due to the Africanized honeybees as their geographic area continues to expand within the United States. As an example, in Venezuela in 1978, before the Africanized honeybees arrived, there were 12 deaths attributed to bee stings; however, after 1978, there were 100 deaths per year. Stings can be treated in the same way; however, in the case of multiple stings, excessive histamine release may result from venom action and not necessarily from an allergic reaction. *Physicians need to be aware of this fact and the possible need to treat for histamine overdose* (56). Victims of these bee attacks usually develop a severe envenomation syndrome characterized by the release of a large amount of cytokines (interleukins [IL] IL-1, IL-6, IL-8) and tumor necrosis factor. Subsequently, such cytokines produce an acute inflammatory response that triggers adverse effects on skeletal muscles, bone marrow, hepatic and renal functions, and cardiovascular, central nervous, and immune systems.

Bumblebees also sting when disturbed; however, they are neither as aggressive nor as prevalent as honeybees. Treatment for stings is the same as for honeybee stings.

Fire Ants

Ants can bite as well as sting; however, most do little harm. One exception is the fire ant, *Solenopsis invicta*, which is endemic in the southeastern United States. The ants measure about 4 to 6 mm long and are reddish brown (red form) or black (black form). Although they look like ordinary ants, their head is a lighter color than the rest of the body. The presence of fire ants can usually be recognized by seeing their characteristic mounds, which are earthen mounds with a diameter of 24 in. and a height of 18 to 24 in. surrounded by relatively undisturbed vegetation (Fig. 35.34, 35.35, and 35.36) (56). The mounds have a freshly tilled appearance. When even slightly disturbed, the ants tend to boil out of their mounds. The workers attach to the skin by biting with their mandibles and then lowering their abdomen to inject the stinger; thus, the victim receives both a bite and a sting. The symptom of a sting has been described as a "burning itch." Within about 24 h, a pustule develops and may remain for about a week (Fig. 35.6). Although some individuals have sustained thousands of stings with no toxic or allergic reactions, some people with hypersensitivity to fire ant venom may have severe reactions from just a few stings. At least 250 million acres within the United States are infested, now reaching as far west as New Mexico, Arizona, and California. In some heavily infested areas, 50 to 400 or more mature colonies may be found per acre. There are actually two species, *S. invicta*, the red form imported from Brazil, and *S. richteri*, the black form imported from Uruguay. The geographic range for *S. richteri* in the United States is much more limited, occurring in northeastern Mississippi, northwestern Alabama, and part of Tennessee (6).

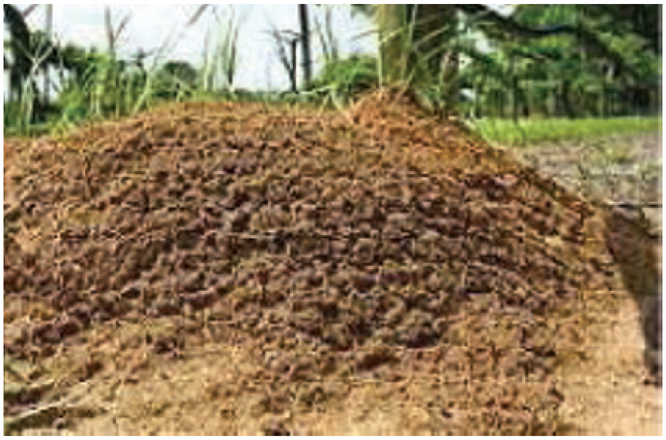


Figure 35.36 Typical mound of the fire ant; the height can reach 2 ft. Often the mound looks like the dirt has just been tilled. (Courtesy of the U.S. Department of Agriculture.) doi:10.1128/9781555819002.ch35.f36

Harvester Ants

Harvester ants, *Pogonomyrmex* spp., are ant species that sting both animals and humans. These ants are red to dark brown and are two or three times as large as fire ants. Harvester ant mounds are usually flat or slightly elevated, measure about 3 to 9 ft in diameter, and are surrounded by no vegetation (Fig. 35.37). There is only one harvester ant species east of the Mississippi River, and it is found

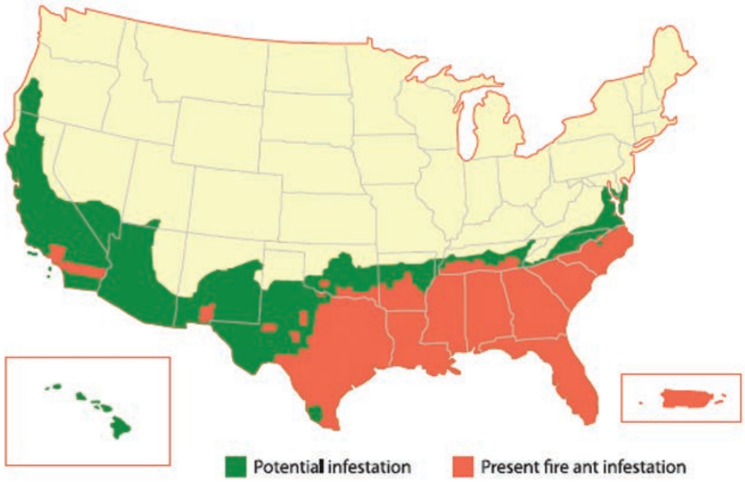

Figure 35.35 Present and potential ranges of imported fire ant infestation (courtesy of the CDC Public Health Image Library, U.S. Department of Agriculture). doi:10.1128/9781555819002.ch35.f35

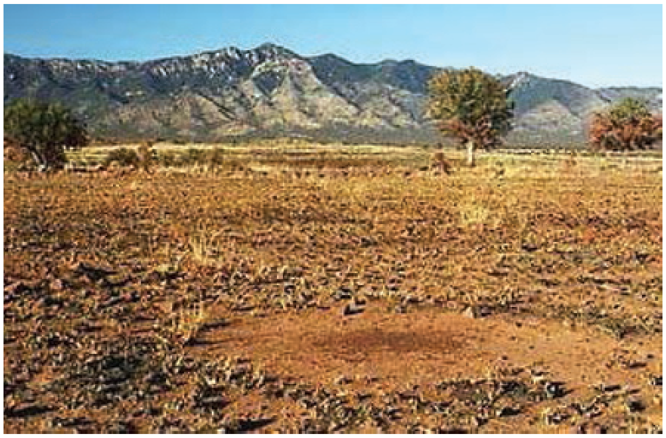

Figure 35.37 Typical flat mound of the harvester ant; the flat area with no vegetation can range from 3 to 9 ft. (Courtesy of the U.S. Department of Agriculture.)
doi:10.1128/9781555819002.ch35.f37

throughout the Southeast. In the western United States, about 20 species occur; three of the most serious are the red harvester ant (*P. barbatus*), the California harvester ant (*P. californicus*), and the Western harvester ant (*P. occidentalis*). The reaction to harvester ant stings is not always localized but may spread along the lymphatics. This causes severe pain in the lymph nodes in the axilla or groin some time after the pain from the original sting has gone. Systemic allergic reactions tend to be uncommon.

Order Blattaria (Cockroaches)

Cockroaches are among the most ubiquitous pests throughout the world. A number of the 3,500 species have become adapted to living with humans and are referred to as "domestic" species that will breed anywhere. They are very active, nocturnal insects; anyone who has turned on the lights in the kitchen late at night remembers the surprise at seeing all the visitors! Cockroaches are flattened dorsoventrally and have long, multisegmented antennae, biting mouthparts, two pairs of wings, two cerci, and legs adapted for running (55). They feed on human food, excreta, sputa, and even bookbindings, paper, and leather.

Mechanical Transmission of Organisms. Although certain flies and dung beetles have been implicated as mechanical vectors of *Cryptosporidium* oocysts, there is every reason to suspect that cockroaches could also do the same (5). When cockroaches feed on infected material, their mouthparts and legs become contaminated; they can then introduce these contaminants into human surroundings. Also, organisms can pass through the cockroach gut and remain fully viable. Some investigators have speculated that the cockroach may be a more significant vector of human pathogens than houseflies, transmitting viruses, bacteria, and parasites to human hosts. In one study of 234 cockroaches trapped from different sites (toilets, parlors, kitchens, and bedrooms) in houses with pit latrines and water systems, bacterial, fungal, and parasitic isolates were identical irrespective of the site and included *Escherichia coli*, *Klebsiella pneumoniae*, *Proteus vulgaris*, *Proteus mirabilis*, *Citrobacter freundii*, *Enterobacter cloacae*, *Salmonella* spp., *Pseudomonas aeruginosa*, *Serratia marcescens*, *Staphylococcus aureus*, *S. faecalis*, *S. epidermidis*, *Aeromonas* spp., *Candida* spp., *Rhizopus* spp., *Aspergillus* spp., and *Mucor* spp.; cysts of *Entamoeba histolytica* and of *Balantidium coli*; oocysts of *Cryptosporidium* spp., *Cyclospora cayetanensis*, and *Cystoisospora belli*; ova of *Ascaris lumbricoides*, *Ancylostoma duodenale*, *Enterobius vermicularis*, and *Trichuris trichiura*; and larvae of *Strongyloides stercoralis* (5). Some humans also become allergic to cockroach allergens. Control involves good sanitation, prevention of new entry, and a combination of various pesticides including bait, strips, sprays, and dusts.

Several important species include *Blatella germanica* (German cockroach), *Blatta orientalis* (Oriental cockroach), *Supella longipalpa* (brown-banded cockroach), and *Periplaneta americana* (American cockroach) (Fig. 35.38). These different cockroaches prefer different habitats, with some preferring warm, moist conditions (German cockroach) and others preferring cooler locations (Oriental cockroach). The most common cockroach throughout the United States is the German cockroach, which can be found infesting most buildings. Adult German and brown-banded cockroaches are approximately 15 mm long, while the American and Oriental cockroaches measure 30 to 50 mm long.

Cockroach Allergens. In addition to the mechanical transmission of many types of bacteria, fungi, and parasites, the excrement and cast skins of cockroaches contain a number of antigens that cause allergic responses. Urban allergens include the cockroach, mouse, and rat. Cockroach allergy is common among inner city children with asthma, and exposure to cockroach allergen is associated with more severe disease. Cockroach allergens are one of the major etiologic risk factors for IgE-mediated allergic respiratory illness throughout the world. A high prevalence of cockroach hypersensitivity in atopic (20 to 55%) and asthmatic (49 to 60%) populations has been documented (5). In a survey of day care facilities in North Carolina, detectable levels of indoor allergens were commonly found, including cockroach allergens. For many young children and day care staff, day care facilities might be a source of clinically relevant exposures to indoor allergens. Cockroach allergen avoidance begins with effective pest control, followed by thorough and repeated cleaning. At least 1 to

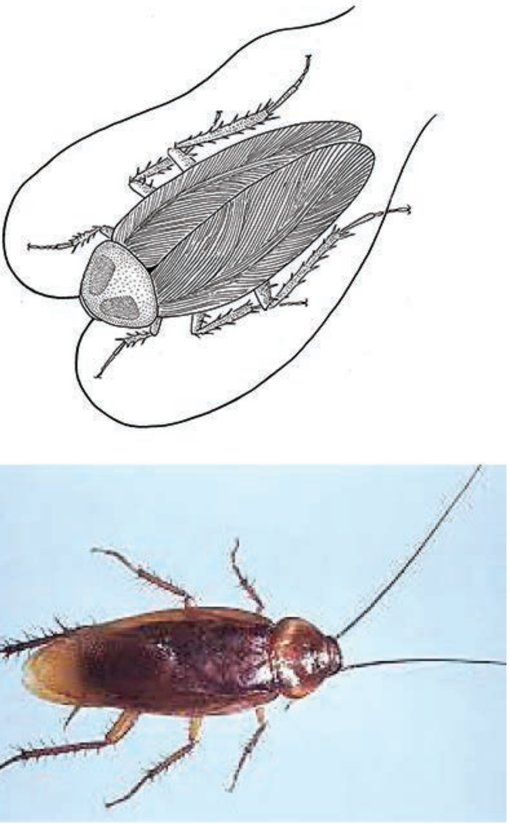

Figure 35.38 American cockroach (*Periplaneta americana*). (Upper, illustration by Sharon Belkin; lower, courtesy of the CDC Public Health Image Library.)
doi:10.1128/9781555819002.ch35.f38

2 months is required to eliminate cockroaches, and an additional 4 to 6 months is required to remove residual allergen. Once allergen levels have been reduced, continued efforts are necessary to maintain the home free of allergen sources. The school environment can also be an important site of exposure to cat, dog, dust mite, and cockroach allergens, which have been detected in the settled dust of many schools. In industrialized nations, the school environment has a lower potential for exposure than the home environment, but schools are significant for allergic individuals whose home environment has been addressed to the extent possible. From a public health perspective, the school environment should be considered a target for primary and secondary prevention.

Class Arachnida (Ticks, Mites, Spiders, and Scorpions)

Subclass Acari (Ticks, Mites, and Chiggers)

The subclass Acari contains the soft and hard ticks, mites, and chiggers.

Soft and Hard Ticks

Although there are over 800 species of ticks throughout the world, only two families of ticks, *Ixodidae* (hard ticks) and *Argasidae* (soft ticks), are known to transmit diseases or illness to humans. The soft and hard ticks are ectoparasites adapted to blood-sucking (mammals, birds, and reptiles) (57–59). There is no hard dorsal plate in the soft tick, and the mouth parts are ventral to the anterior extremity (Fig. 35.39; Tables 35.6, 35.7, and 35.8). In the hard tick, the dorsal plate or shield covers the entire surface of the male but only the anterior portion of the female (Fig. 35.40 and 35.41). The dorsal surface of a tick's body often has color patterns, furrows, or sculpting that allows species determination.

Tick Paralysis. Ticks are responsible for the transmission of viral, bacterial, rickettsial, and protozoan (*Babesia* spp.) pathogens. The salivary secretions of some ticks may produce systemic toxemia (tick paralysis) that can cause death. Paralysis can occur from a tick attached to any part of the body, although the symptoms may be more serious when the tick injects toxin at the back of the neck or along the spinal column. Symptoms may include elevated temperature, rapid ascending flaccid paralysis, and difficulty in breathing and swallowing, and death may result. The onset may be very sudden, within 24 h, or may not appear for several days. The most likely tick involved is *Dermacentor andersoni*, the Rocky Mountain wood tick. Human cases tend to occur in the spring and early summer, when ticks are most active and are seeking a blood meal. Tick paralysis can be particularly dangerous for children; after playing in underbrush or bushes, the child should have all clothing removed and should be carefully examined for the presence of ticks, particularly around the neck and shoulder area (under the hair). The most likely geographic area is in western Montana, Idaho, and Oregon, although cases have been reported from other states including Georgia, Tennessee, Louisiana, and the Atlantic seaboard. Ticks in the genera *Amblyomma* and *Dermacentor* have been involved in cases outside of the western United States, while in other parts of the world *Ixodes*, *Rhipicephalus*, *Hyalomma*, and *Ornithodoros* have been implicated in tick paralysis.

Soft Ticks. The soft ticks have an oval or pear-shaped outline with the anterior body region broadly rounded. The mouthparts are difficult to see from a dorsal view. The soft ticks are inornate and have a granulated leathery appearance. They lack a scutum; however, most species have a centrally located dorsal plate which is covered by tiny mammillae, ridge structures that protrude above the cuticle surface. Subcircular depressions termed discs, representing sites of muscle attachment, occur in characteristic patterns over the dorsal and ventral surface (Fig. 35.39).

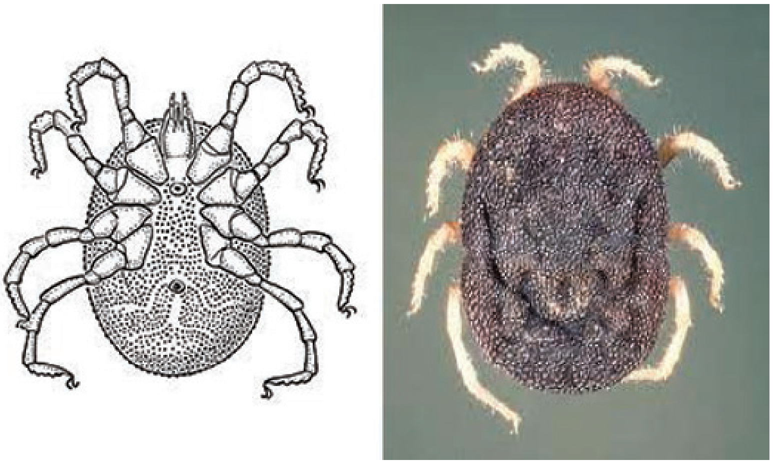

Figure 35.39 (Left) Soft tick, ~12 mm (illustration by Sharon Belkin, based on an illustration from Najarian HH, *Textbook of Medical Parasitology*, The Williams & Wilkins Co, Baltimore, MD, 1967). (Right) Soft tick; note the mouth parts can normally be seen only from the ventral side (courtesy of the CDC Public Health Image Library). doi:10.1128/9781555819002.ch35.f39

Soft ticks feed for short periods of time on their hosts, very similar to that of fleas or bedbugs. The cuticle of soft ticks stretches but does not grow to accommodate the large volume of blood ingested, which may be anywhere from 5 to 10 times their unfed body weight. Soft ticks are considered to be more dangerous than hard ticks because they can transmit disease within minutes of a bite. Differentiation between the soft ticks and hard ticks is relatively easy once an engorged hard tick is recognized as such.

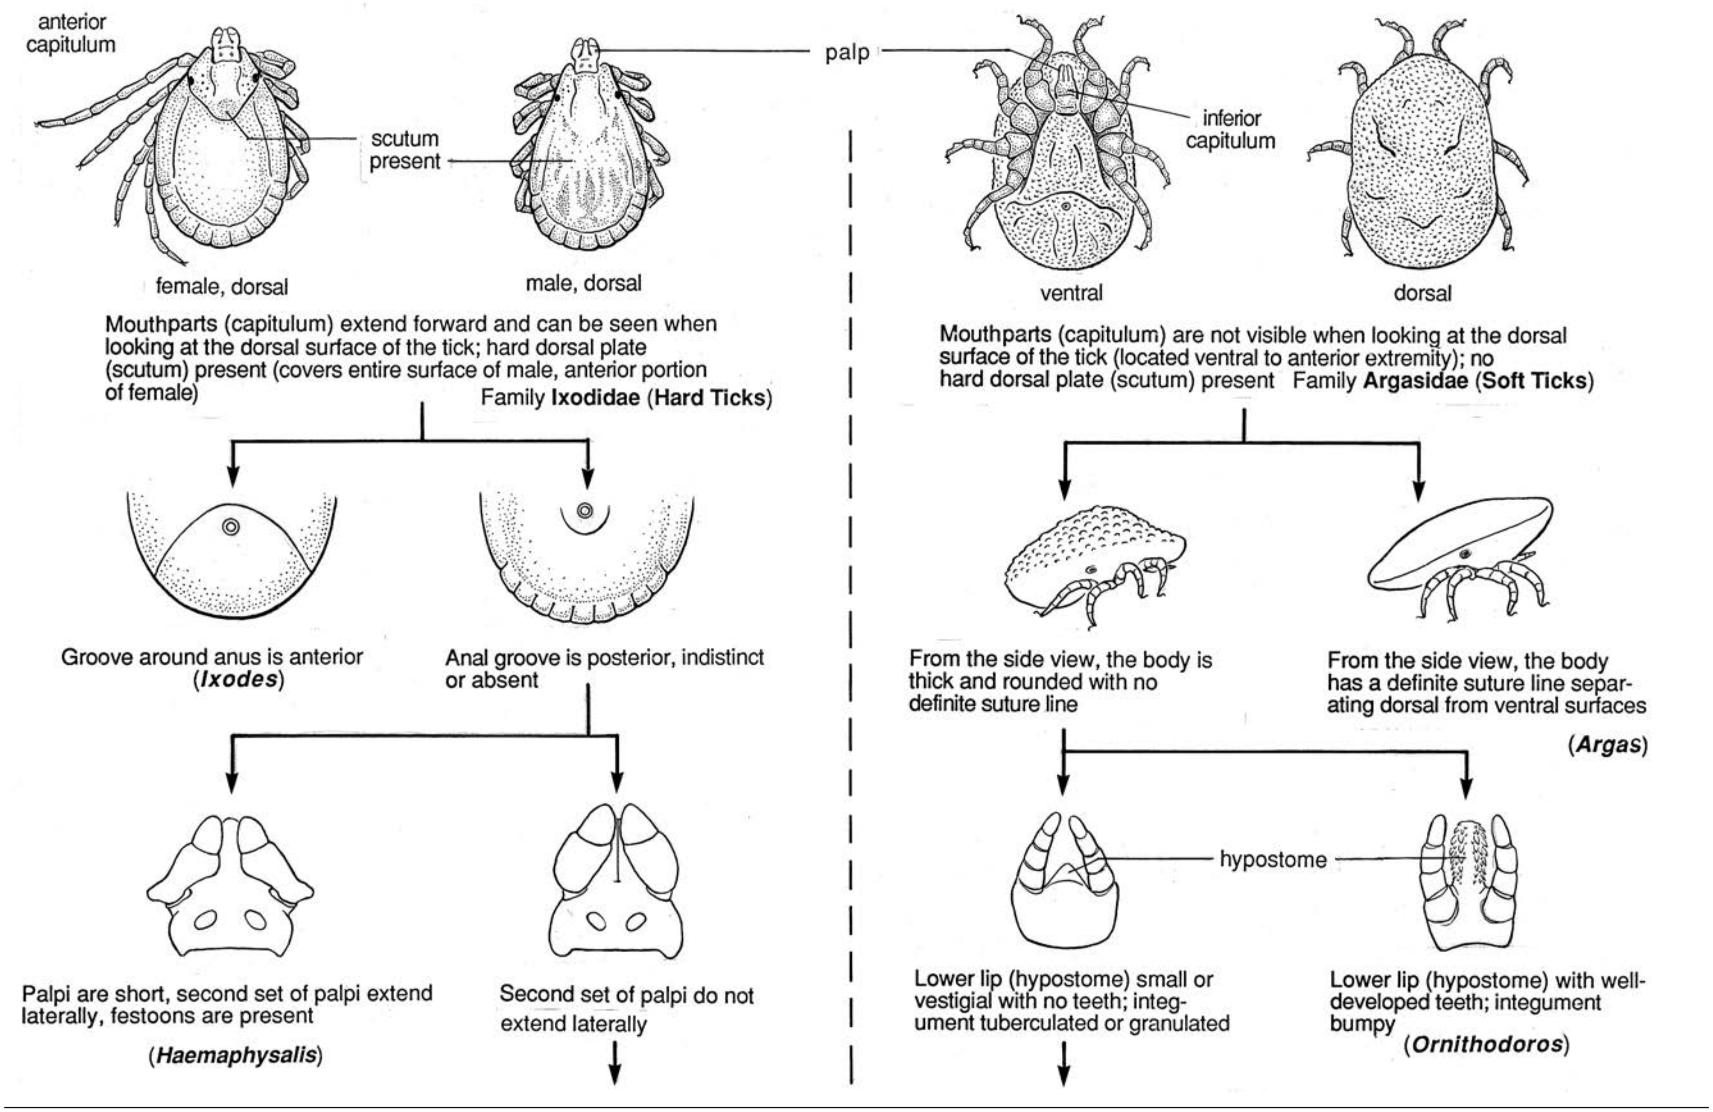
Hard Ticks. Hard ticks are found in habitats that support large numbers of vertebrate hosts such as small mammals, especially mice, ground-dwelling birds, and lizards. Tick larvae tend to remain on the ground, where they encounter potential hosts, but larvae of some species can feed on humans. Nymphs remain on the ground or climb grassy vegetation from which they are able to grasp a passing host, including small to medium-sized mammals, but nymphs of a few species are attracted to larger hosts, including pets and humans. Adult ticks may remain on the ground, but more commonly climb up vegetation, from which they grasp a passing host. They often can be seen at the tops of grass blades or on lower leaves of bushes engaging in "questing." Questing is a behavior in which the tick reaches upward with waving front legs ahead of an approaching host. Adult ticks tend to feed on larger mammalian hosts such as deer, livestock, dogs, and humans.

Ticks feed by making a cut in the host epidermis, inserting the hypostome into the cut, and attaching to the host. Blood is kept flowing through the use of an anticoagulant from the salivary glands of the tick. Some hard ticks form a cement cone around the mouthparts and bite site. Female hard ticks undergo a growth feeding phase characterized by slow continuous blood intake, followed by a rapid engorgement phase occurring during the last 24 h of attachment. Hard ticks have the ability to expand considerably, often resembling a soft tick. Many hard ticks attach themselves to grasses or weeds, waiting for a host to come along; they are also attracted to carbon dioxide. Hard ticks are generally found in brushy, wooded, or weedy areas containing deer, cattle, dogs, small mammals, and other hosts. Hard ticks have to conserve moisture, and so their activity and survival are influenced by temperature as well as humidity. Transmission of a pathogen typically does not occur until an infected tick has attached and fed for at least 24 hours, and transmission of some pathogens does not begin until an infected tick has fed for 48 hours or more.

Identification to the species level among the hard ticks can be difficult. Currently there is a great deal of interest in identifying the ticks that transmit Lyme disease. In the northeastern United States, the primary vector for Lyme disease caused by *Borrelia burgdorferi* is *Ixodes scapularis*, the black-legged tick (formerly known as *Ixodes dammini*, although it now appears that they are a single species) (60, 61). The life cycle takes 2 to 4 years. Larvae are active from August to October, when they are feeding on *Peromyscus leucopus*, the white-footed mouse. The infection rate in mice is approximately 25% and occurs from May to June. Human cases tend to peak in July. A tick needs to feed for 48 h for successful transmission of *B. burgdorferi*; although 50 to 100% of the adult *I. scapularis* ticks are infected, most are removed from the human host prior to 48 h. *I. scapularis* is found in dense brush on islands off the northeast coast and in heavily forested areas inland. In Wisconsin, these ticks occur in areas between the northern coniferous-hardwood and southern deciduous forests.

In western North America, the primary vector of *B. burgdorferi* is *Ixodes pacificus*, the western black-legged tick. These ticks range from sea level to >6,000 ft and are found from California to British Columbia and east to Nevada, Utah, and Idaho. Larvae and nymphs are active from March to June, and adults are found on humans from November to May. The infection rate of *I. pacificus* is

TABLE 35.6 Identification of the more common hard and soft ticks. (Illustration by Sharon Belkin; adapted from National Communicable Disease Center Pictorial Keys, 1969.)



Mouthparts (capitulum) extend forward and can be seen when looking at the dorsal surface of the tick; hard dorsal plate (scutum) present (covers entire surface of male, anterior portion of female) Family **Ixodidae** (**Hard Ticks**)

Groove around anus is anterior (***Ixodes***)

Anal groove is posterior, indistinct or absent

Palpi are short, second set of palpi extend laterally, festoons are present (***Haemaphysalis***)

Second set of palpi do not extend laterally

Mouthparts (capitulum) are not visible when looking at the dorsal surface of the tick (located ventral to anterior extremity); no hard dorsal plate (scutum) present Family **Argasidae** (**Soft Ticks**)

From the side view, the body is thick and rounded with no definite suture line

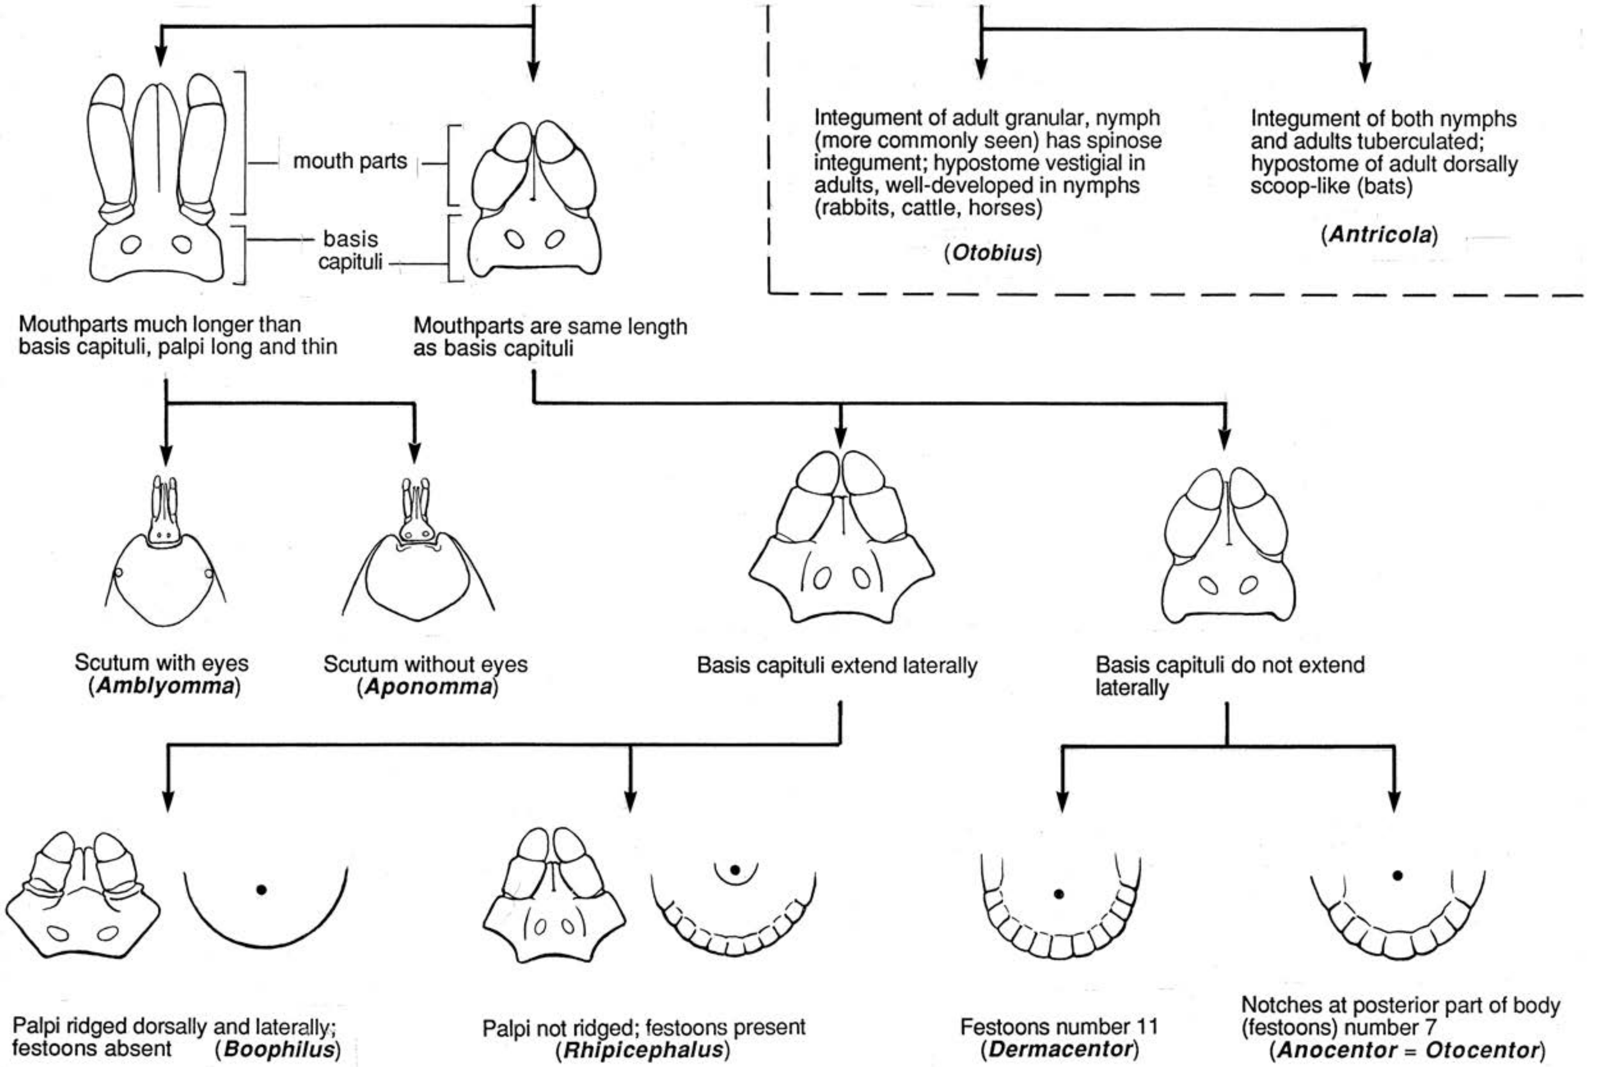
From the side view, the body has a definite suture line separating dorsal from ventral surfaces (***Argas***)

Lower lip (hypostome) small or vestigial with no teeth; integument tuberculated or granulated

Lower lip (hypostome) with well-developed teeth; integument bumpy (***Ornithodoros***)

(continued)

TABLE 35.6 Identification of the more common hard and soft ticks. (Illustration by Sharon Belkin; adapted from National Communicable Disease Center Pictorial Keys, 1969.) *(continued)*



mouth parts
basis capituli
Mouthparts much longer than basis capituli, palpi long and thin
Mouthparts are same length as basis capituli
Integument of adult granular, nymph (more commonly seen) has spinose integument; hypostome vestigial in adults, well-developed in nymphs (rabbits, cattle, horses)
(*Otobius*)
Integument of both nymphs and adults tuberculated; hypostome of adult dorsally scoop-like (bats)
(*Antricola*)
Scutum with eyes (*Amblyomma*)
Scutum without eyes (*Aponomma*)
Basis capituli extend laterally
Basis capituli do not extend laterally
Palpi ridged dorsally and laterally; festoons absent (*Boophilus*)
Palpi not ridged; festoons present (*Rhipicephalus*)
Festoons number 11 (*Dermacentor*)
Notches at posterior part of body (festoons) number 7 (*Anocentor* = *Otocentor*)

TABLE 35.7 Differences between hard ticks and soft ticks

Feature	Hard Tick	Soft Tick
Scutum (dorsal shield)	Present	Absent, soft, leathery exoskeleton
Capitulum (mouth parts)	Anterior, visible from above	Ventral, not visible from above
Nymphal stages	One	Several
Adult feeding time	Several days	30–60 min
Female blood meals	One	Several
Egg-laying events	One	Several
Total eggs laid	3,000–8,000	400–500
Feeding habits	Feed several times during each stage	Feed only once during each stage
Feeding accommodation	Cuticle grows to accommodate large volume of blood ingested	Cuticle expands, but does not grow to accommodate large volume of blood ingested
Life span	Less than a year to >3 years	Several years
Genera	*Amblyomma*, *Dermacentor*, *Ixodes*, *Rhipicephalus*	*Argas*, *Antricola*, *Ornithodoros*, *Otobius*

TABLE 35.8 Descriptions of some of the more common hard ticks found in the United States

Tick	Description	Comments
Amblyomma americanum (Lone Star tick)	Reddish-brown tick species; adult stages have long mouth parts visible from above; adult females have distinct white spot on their back (scutum); males have no single spot but have inverted horseshoe-shaped markings at the posterior edge of their dorsal side	Central Texas east to the Atlantic; north to Iowa and New York; northern Mexico; probably most aggressive and common tick in southern United States; transmits tularemia, possibly ehrlichiosis
Amblyomma maculatum (Gulf Coast tick)	Somewhat similar to American dog tick, except with metallic instead of white markings, long mouth parts; adult females with metallic white or gold markings on scutum, males with numerous, mostly connected linear spots of golden white	Portions of Atlantic and Gulf Coast areas (100–200 miles inland, south into Mexico); increasingly a pest in southern United States; nuisance only
Dermacentor andersoni (Rocky Mountain wood tick)	Adults have shorter mouth parts than *Amblyomma*; usually dark brown or black with bright white markings on the scutum	Western counties of Nebraska and Black Hills of South Dakota to Cascade and Sierra Nevada Mountains; northern Arizona and northern New Mexico to British Columbia, Alberta, and Saskatchewan; transmits RMSF,[a] Colorado tick fever, tularemia; tick paralysis in United States and Canada
Dermacentor variabilis (American dog tick)	Adults dark brown or black; short, rounded mouth parts; dull or bright white markings on scutum	Medically important; primary vector of RMSF in the central and eastern United States; transmits tularemia, maybe tick paralysis; deticking dogs may lead to infection
Ixodes pacificus (western black-legged tick)	No white markings on dorsal side, no eyes or festoons, adults dark brown; moderately long mouth parts; appears almost identical to *I. scapularis*	Along Pacific coastal margins of British Columbia and the United States, possibly extending into Baja California and Mexico; most cases of Lyme disease in California are transmitted by this tick
Ixodes scapularis (black-legged tick)	Adults have no eyes, festoons, or white markings on dorsal side; dark brown but may appear light brown or orangeish	Northern form in New England states and New York, south into New Jersey, Virginia, and Maryland; upper Midwest and Ontario; southern form around southern Atlantic Coast states, Texas, Oklahoma, and Mexico
Rhipicephalus sanguineus (brown dog tick)	Light to dark brown, no white markings on dorsal side; have both festoons and eyes	Most widely distributed tick; almost worldwide in Western Hemisphere; transmits RMSF; found indoors around pet bedding areas; strong tendency to crawl upward (walls of infested houses)

[a] RMSF, Rocky Mountain spotted fever.

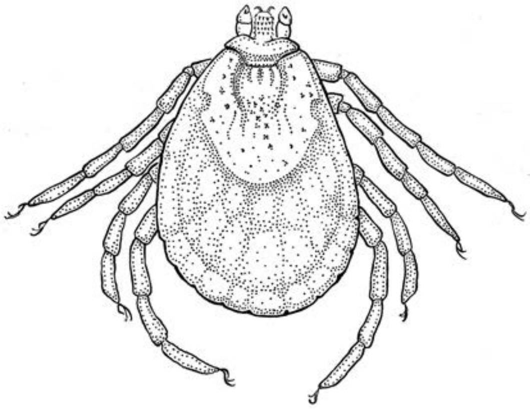


Figure 35.40 Hard tick, 4 to 10 mm. (Illustration by Sharon Belkin, based on an illustration from Najarian HH, *Textbook of Medical Parasitology*, The Williams & Wilkins Co, Baltimore, MD, 1967.) doi:10.1128/9781555819002.ch35.f40

about 1.5%. Studies looking at the prevalence of anti-arthropod saliva antibodies among residents in a high-risk community revealed a 79% positive rate compared with control groups (62). In the San Francisco Bay Area, the figure was 36%. In the study group, seropositivities for *I. pacificus* and for *B. burgdorferi* were significantly correlated. Experimental and field evaluations of two acaricides for control of *I. pacificus* in northern California appear very promising, and these substances can be a beneficial component of an overall control program (63).

The morphologic differences between *I. pacificus* and *I. scapularis* are minimal (Fig. 35.42 and 35.43). Both species have no white markings on their dorsal side and no eyes or festoons. Adults are dark brown, and the mouthparts are moderately long. Occasionally, *I. scapularis* appears light brown or orangish from the dorsal view (64). The difference between the nymph and the adult can be seen in Fig. 35.44. Descriptions of the more common ticks are given in Table 35.6.

Tick Removal. The proper way to remove a soft tick is to use a pair of curved tweezers. Wash your hands and put on a pair of disposable gloves. Grasp the tick at the base closest to the skin with the tweezers tips. Slowly pull the tick out, making sure not to yank, squeeze or twist it. Twisting or turning the tick does not make removal easier because the mouthparts are barbed. If the head of the tick remains embedded in the skin, apply a warm compress to help draw it out. Seek medical assistance if you cannot remove all the tick's parts. Wash the site with soap and water or a mild disinfectant. Do not cover the soft tick with rubbing alcohol, clear nail polish, or lighter fluid before removing it, and do not burn the tick with a match. These methods are dangerous and ineffective; worse, they can actually cause the tick to regurgitate into the body, leading to a greater chance of infection and disease transmission. Pending any medical problems or symptoms of a tick-borne illness, it is recommended that the tick be saved in a plastic bag or vial, stored in the freezer, and saved for several months.

Itch Mites (Mange Mites), Follicle Mites, and Dust Mites

Itch Mite. Dating back to over 2,500 years ago, scabies was known from the time of the Greeks and Romans through the Middle Ages as the "itch." Although the disease was acknowledged by numerous cultures over several eras, the cause of the infliction was never clearly deter-

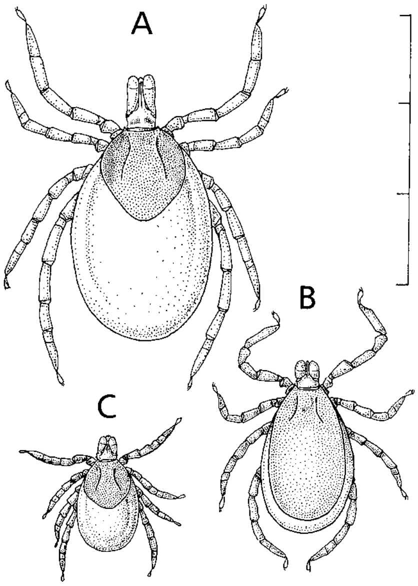

Figure 35.42 *Ixodes* spp. Diagram of the female (A) and male (B) adult ticks and the nymph (C) (bar, 3 mm). (Illustration by Sharon Belkin, based on information in reference 58.) doi:10.1128/9781555819002.ch35.f42

mined until Giovanni Cosimo Bonomo accomplished this in 1687. Several genera infect the skin of mammals, with *Sarcoptes scabiei* being found in humans, although some mange mites of animals occasionally cause a pruritic rash in humans (65). *S. scabiei* is microscopic and lives in cutaneous burrows, where the fertilized female deposits eggs (Fig. 35.45 through 35.49). Scabies is transmitted by close contact with infested individuals, including touching, shaking hands, sexual contact, and contact in day care centers with children and the elderly. Scabies is common among those in overcrowded conditions and has been associated with immigrants, poor hygiene, poor nutritional status, homelessness, dementia, and sexual contact.The usual skin sites that are susceptible to infection are the interdigital spaces, backs of the hands, elbows, axillae, groin, breasts, umbilicus, penis, shoulder blades, small of the back, and buttocks (Fig. 35.46 through 35.48) (9). The outstanding clinical symptom is intense itching. Scratching commonly causes weeping and bleeding and sometimes leads to secondary infection. A form of the infestation, called crusted scabies, can occur in immunosuppressed or anergic individuals; many mites are present in keratotic excrescences on the body and extremities, but pruritus is usually absent (Fig. 35.48). This infestation is highly contagious and has been reported to be the cause of hospital epidemics. Scabies occurs worldwide, with at least 300 million cases each year. Oral ivermectin, at a dose of 300 µg/kg, given as a single dose and repeated after 7 days, proved effective for the treatment and prophylaxis of scabies in an infected institutional environment (66).

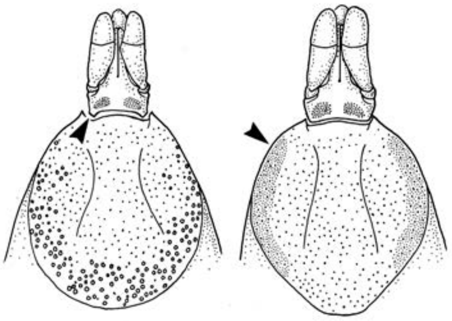

Figure 35.43 (Left) *Ixodes scapularis*. The scutum (the dorsal shield, which is small in the female and almost covers the dorsal surface in the male) and the terminal capitulum, which is attached to the anterior end of the body of *Ixodidae*. Note that the scutum is nearly circular, with punctuations larger peripherally. The cornua (arrowhead) is small but definite for *I. scapularis*. (Right) *Ixodes pacificus*. Scutum and terminal capitulum. Note that the scutum is oval with uniformly distributed small punctuations (arrowhead), and the cornua is absent. (Illustration by Sharon Belkin, based on information in reference 58.) doi:10.1128/9781555819002.ch35.f43

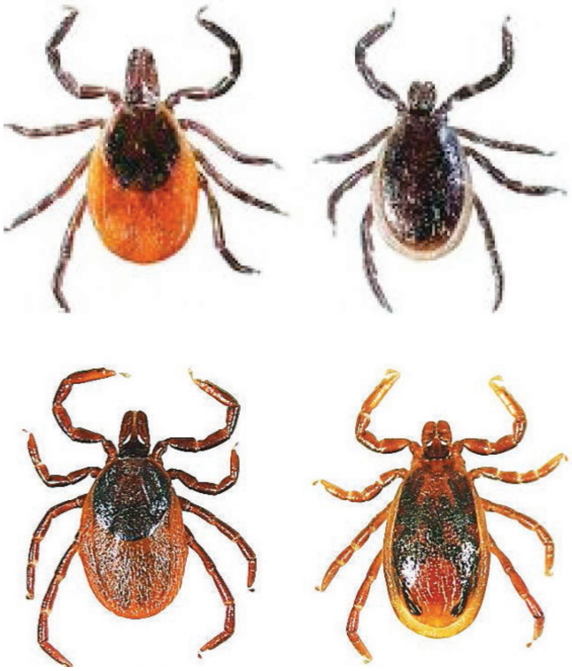

Figure 35.44 (Upper) *Ixodes scapularis*: (left) adult female; (right) adult male. Note that there are no white markings on the dorsal surface and no eyes or festoons (Table 35.6). (Lower) *Ixodes pacificus*: (left) adult female; (right) adult male. Note the mouthparts are almost identical, but color variation is less common with *I. scapularis*. (Courtesy of the CDC Public Health Image Library.) doi:10.1128/9781555819002.ch35.f44

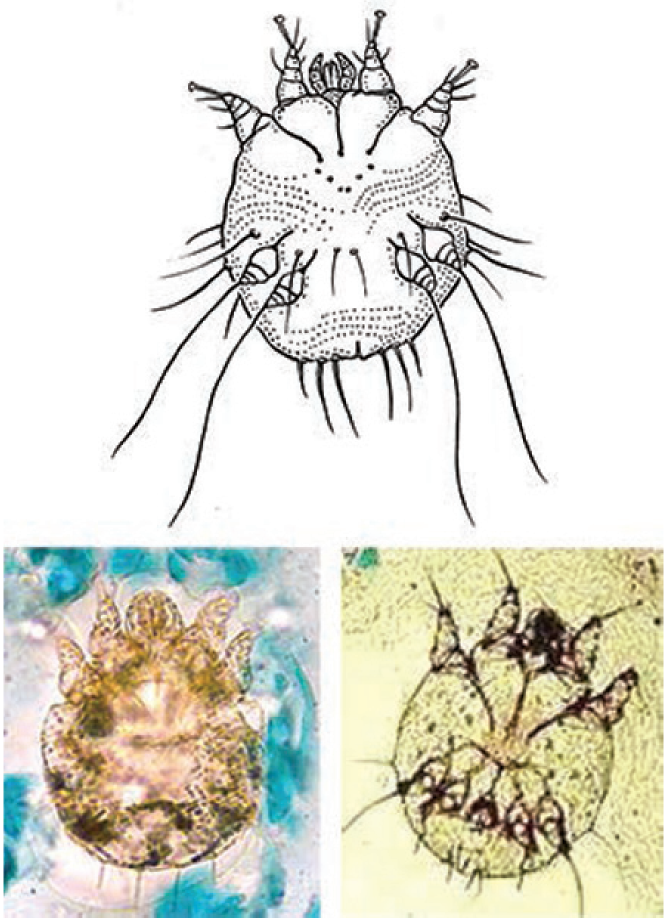

Figure 35.45 Itch mite (*Sarcoptes* sp.). (Top) Adult mite, ventral surface, ~0.25 mm (illustration by Sharon Belkin, based on an illustration from Najarian HH, *Textbook of Medical Parasitology*, The Williams & Wilkins Co, Baltimore, MD, 1967). (Bottom, left) Adult mite, dorsal surface; (right) adult mite, ventral surface; note the legs are now visible. (Courtesy of the CDC Public Health Image Library.) doi:10.1128/9781555819002.ch35.f45

The most common symptoms are produced by the host immune reaction to burrowed mites and their products. Pruritus and rash may take up to 2 to 6+ weeks to develop after initial exposure to the scabies mite. For this reason, the early clinical presentation of scabies should be detected as soon as possible to prevent the spread of infestation. Skin scraping with dermoscopy is implicated as the diagnostic method of choice for scabies at the present time. Dermoscopy is especially useful in diagnosis of incognito scabies (67). In addition, the presence of visible burrows could be a reliable positive marker of scabies in the absence of dermoscopy or microscopy data. Specific techniques for recovery of the mites are listed below.

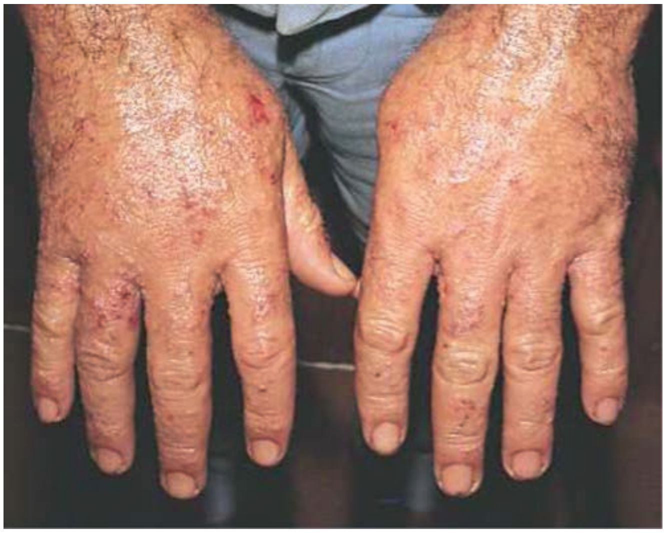

Figure 35.46 Scabies of hand. Lesions are complicated by scratching and secondary bacterial infection. (Armed Forces Institute of Pathology photograph.)
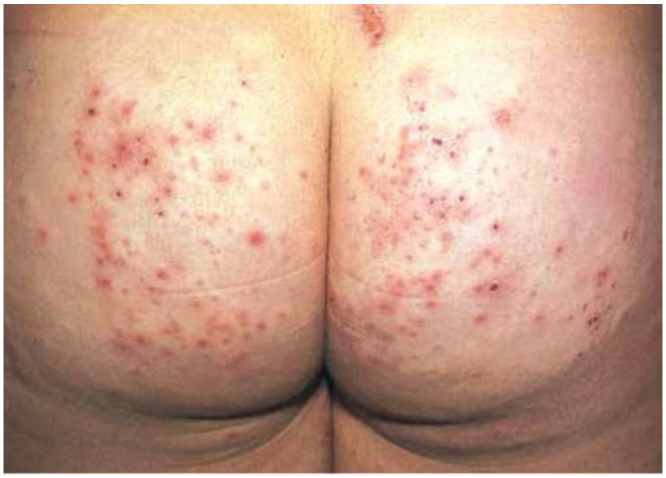
doi:10.1128/9781555819002.ch35.f46

Skin-scraping technique. The diagnosis can be confirmed by demonstration of the mites, eggs, or scybala (fecal pellets). Because the mites are located under the surface of the skin, scrapings must be made from the infected area.

1. Place a drop of mineral oil on a sterile scalpel blade. (Mineral oil is preferred to potassium hydroxide solution or water. Mites adhere to the oil, skin scales mix with the oil, the refractility differences are greater between the mite and the oil, and the oil does not dissolve fecal pellets.)
2. Allow some of the oil to flow onto the papule.

Figure 35.47 Scabies of buttocks of a Brazilian child. There is evidence of scratching and secondary bacterial infection. (Armed Forces Institute of Pathology photograph.)
doi:10.1128/9781555819002.ch35.f47



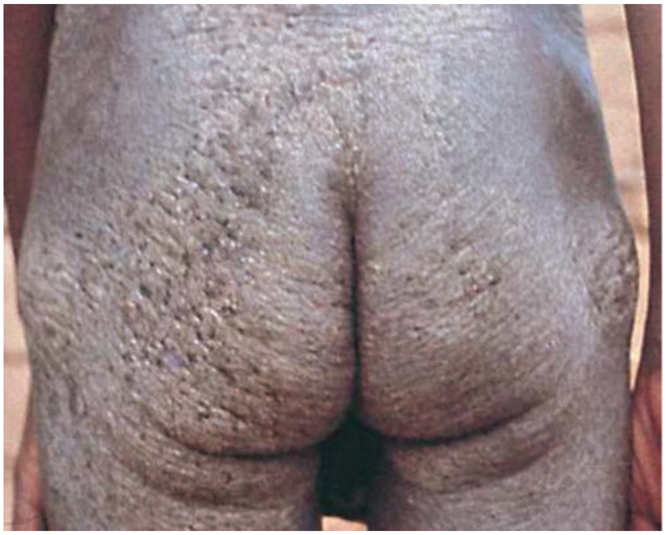


Figure 35.48 Crusted scabies over the buttocks of a 19-year-old Congolese man. The patient was chronically ill, suggesting immunosuppression. Lesions are papulosquamous and excoriated. Scaling and crusting were severe about the elbows and from the lower trunk to the knees. (Armed Forces Institute of Pathology photograph.) doi:10.1128/9781555819002.ch35.f48

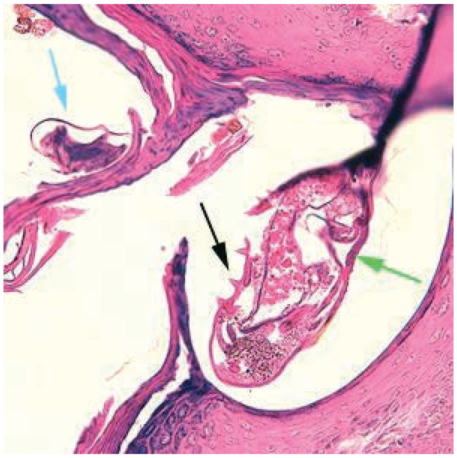
3. Scrape vigorously six or seven times to remove the top of the papule. (There should be tiny flecks of blood in the oil.)
4. Transfer the oil and scraped material to a glass slide (an applicator stick can be used).
5. Add 1 or 2 extra drops of mineral oil to the slide and stir the mixture. Any large clumps can be crushed to expose hidden mites.
6. Place a coverslip on the slide and examine (first on low power). The adult mites range from approximately 215 to 390 μm in length, depending on sex. The eggs are 170 μm long by 92 μm wide, and the fecal pellets are about 30 by 15 μm. The fecal pellets are yellow-brown.

Figure 35.49 *Sarcoptes scabiei* mites in a skin biopsy, stained with hematoxylin and eosin. An adult (green arrow) and an egg (blue arrow) are visible. Note the presence of cuticular spines (black arrow) on the adult. (Courtesy of the CDC Public Health Image Library.) doi:10.1128/9781555819002.ch35.f49



Plastic box or petri dish method. If mineral oil preparations of skin scrapings fail to demonstrate the mites, the encrusted skin scrapings, etc., can be placed in a small plastic box or small petri dish. The container should be left undisturbed at room temperature for 12 to 24 h. Away from the living host, the mites drop to the bottom of the box or dish and can be seen with a magnifying glass or dissecting microscope.

Follicle Mites. Two species of follicle mites parasitize humans; each has its own particular habitat. *Demodex folliculorum* (294 μm by 55 μm) is found in the hair follicles above the sebaceous glands, and *Demodex brevis* (208 μm by 54 μm) occurs in the sebaceous glands. Both are found in the epidermis of the nose, nasolabial fold, forehead, and adjacent regions of the face; these mites have also been associated with dermatitis of the scalp. These follicle mites can be considered more of a nuisance than a true pathogen and are considered to be harmless saprophytes; symptoms may include a mild rosaceous pruritus and a fibrous tissue response around the mites. *Demodex* sp. has been associated with folliculitis, pityriasis, rosacea, blepharitis, and seborrheic dermatitis. Immunosuppressed patients may develop extensive cutaneous lesions (68).

Estimates of human infection range from 25 to 100%. The two species have similar morphology, with *D. brevis* being somewhat shorter. They are elongated wormlike mites with rudimentary legs (Fig. 35.50 and 35.51). Most humans acquire mites early in life, often by mother-to-child transmission. Adults of both species are tiny, elongate, and vermiform; they have three body divisions: the gnathosoma (short anterior region that contains the mouthparts), podosoma (has four pairs of short stumpy legs), and opisthosoma (long posterior half of the body that tapers to a rounded end).

House Dust Mites. Although house dust mites in the genus *Dermatophagoides* are not commonly seen or submitted to the laboratory for confirmation, it is important to realize that these mites are directly linked to allergic reactivity that can be detected in patients with atopic eczema. Powerful allergens can be found in the mites *D. pteronyssinus* and *D. farinae*, as well as in their fecal pellets and secretions. Allergic rhinitis, asthma, and childhood eczema are attributable to these mites. The mites feed on shed human skin scales, but they also eat mold, fungal spores, pollen grains,

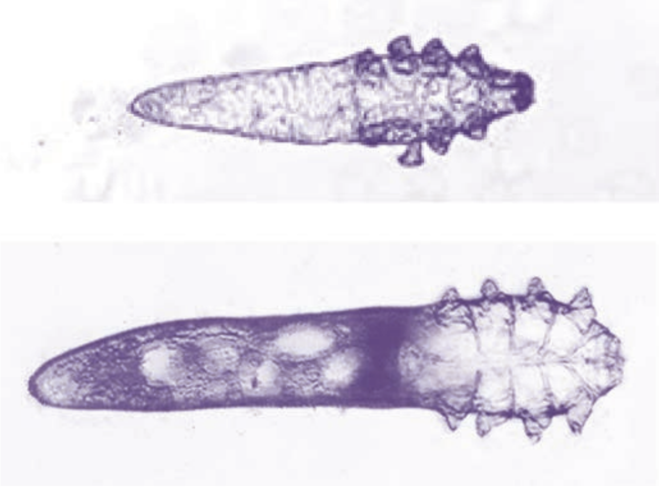


Figure 35.50 Follicle mites. (Upper) *Demodex brevis*; (lower) *D. folliculorum*. Note the rudimentary legs.
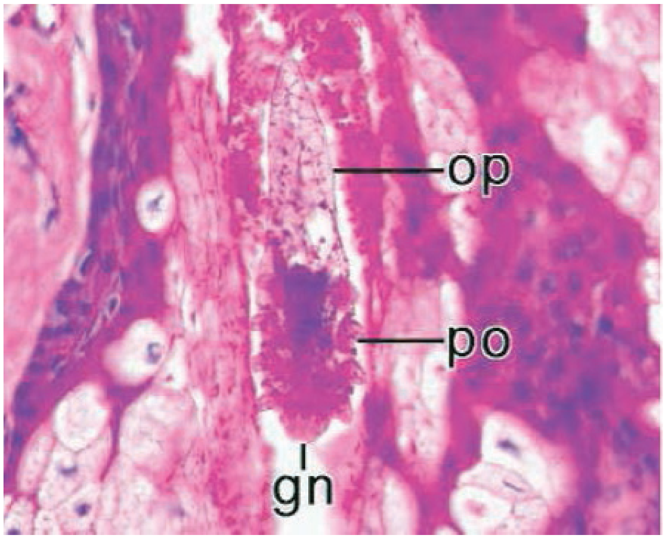
doi:10.1128/9781555819002.ch35.f50

feathers, and animal dander. Active treatment includes Gore-Tex bags for all bedding elements such as the mattress and box springs, a high-power vacuum cleaner, and a spray containing benzyl alcohol and tannic acid to kill mites and denature allergens. These measures are highly effective, particularly the Gore-Tex bed bags (69). This approach was associated with clinical improvement in most patients with atopic eczema, particularly those who were the most severely affected. However, some of the acaricide applications are required at 2- to 3-month intervals to maintain optimal effectiveness (70). Also, treatments are different for different allergens (71). Soft toys are a major source of house dust mites and their allergens, and sleeping with soft toys is a significant risk factor for subsequent sensitization. Treating soft toys by freezing, hot tumble drying, or washing with eucalyptus oil (0.2% to 0.4%) resulted in significant reductions in live mites (72).

Figure 35.51 Section of sebaceous gland showing *Demodex* sp. in hair follicle. Note the short anterior gnathosoma (gn), podosoma with four pairs of legs (po), and long posterior opisthosoma (op). (Armed Forces Institute of Pathology photograph.)
doi:10.1128/9781555819002.ch35.f51



Subclass Araneae (Spiders)

The subclass Araneae contains the spiders, only a few of which can cause pathologic changes in humans. All true spiders produce venom, although few types of venom cause more than a local irritation at the bite site. Those that can cause tissue damage are categorized as causing systemic arachnidism or primarily necrotic arachnidism.

Systemic Arachnidism (Black Widow, Other Widow Spiders)

Widow Spiders. The black widow spider (*Latrodectus mactans* and other species) has the typical shiny black abdomen with a red hourglass shape on the ventral surface (Fig. 35.52). However, it is important to realize that the typical hourglass-shaped marking on the underside of the abdomen may not look like the textbook description, and there are at least five species of "widow" spiders within the United States. Some black widow spiders have bright red hash marks on the dorsal surface in addition to the red hourglass on the underside. Also, the hourglass marking may appear "broken" and not complete (6). There may also be red or white marks on the dorsal side of the abdomen. The color patterns on the underside of the abdomen can vary quite a bit, with what appear to be dots, stripes, or a combination of the two. The immature spiders are tan to gray with little to no black color.

Black widow spiders can cause variable clinical sequelae from local damage to very serious conditions including death. The males and immature black widow spiders bite, but symptoms are mild due to the smaller amount of venom injected. The major component of the venom is alpha-latrotoxin, a protein that causes catecholamine release at adrenergic nerve endings and acetylcholine depletion at motor nerve endings (73). The nervous system is the primary target of alpha-latrotoxin; however, other tissues, such as the heart and lungs, are also susceptible to its toxic effect. Although serious systemic sequelae (abdominal cramps, hypertension, reduced heartbeat and feeble pulse, convulsions, shock, delirium, and death) can occur, uncomplicated recovery is the usual outcome (weakness, myalgia). Following recovery, the individual usually develops complete systemic immunity to subsequent bites, although there may be a local reaction. At the bite site, two small

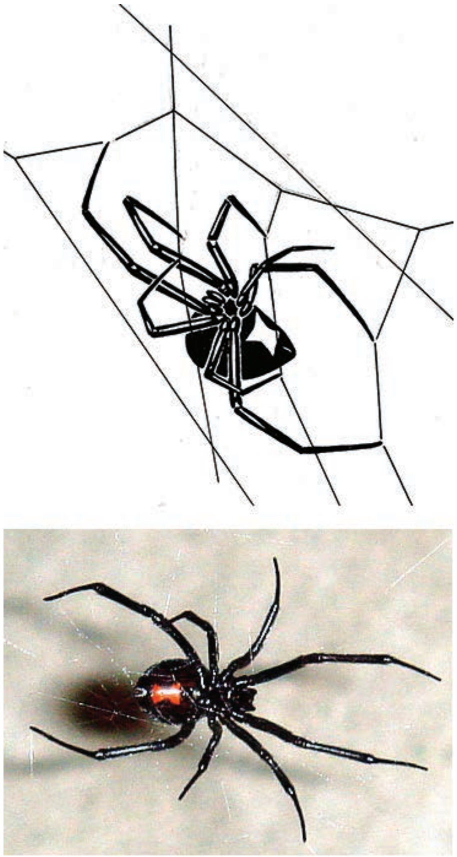


Figure 35.52 Black widow spider (*Latrodectus* sp.), adult, 20 mm. (Upper, illustration by Sharon Belkin; lower, courtesy of the CDC Public Health Image Library.)
doi:10.1128/9781555819002.ch35.f52

red spots may be visible, representing the skin penetration sites.

The wound should be cleaned and ice packs should be applied to limit the spread of the venom. In cases of more severe reactions, the patient should seek medical attention; the use of intravenous solutions, antivenom, and tetanus vaccine are relevant considerations. Children, the elderly, and patients with underlying medical conditions may require hospitalization. In a retrospective study of adverse events following black widow antivenom, results suggest that Black Widow Spider Antivenin (Merck) administration is relatively safe, with mild to moderate adverse effects seen in only a small percentage of patients. There were no deaths or severe allergic reactions identified.

Black widow spiders tend to avoid strong light and prefer dark areas behind or underneath appliances, furniture, closets, etc. These spiders are very reclusive and will not bite unless provoked; generally, they attempt to escape. They are more active in the summer months. After mating, the female kills the male only if she is not well fed, thus ensuring the survival of the eggs; as many as 2,000 offspring may be produced in a single year.

Necrotic Arachnidism (Violin or Brown Recluse Spider, Hobo Spider, Funnel Web Spider, Tarantula Spider)

Violin Spiders. *Loxosceles reclusa*, commonly referred to as the brown recluse or violin spider, is a venomous spider endemic to the southeastern and midwestern United States. *L. reclusa* (and other species) is commonly found inside human habitation rather than in the outdoor areas where the black widow spider can be found (as well as indoors) (74). These spiders are of medium size (0.9 to 1.5 cm long), are yellowish to dark brown, and tend to have a fiddle-shaped marking on the dorsal surface (Fig. 35.53).

Brown recluse spider bites are most often benign and self-limiting, but in a few cases can cause severe necrotic skin lesions (75). Geographical location should be considered when a brown recluse spider bite is suspected; there have been reports of physicians misdiagnosing these bites in areas where *L. reclusa* is not known to be endemic (76). One of the signs of a brown recluse spider bite is the tendency of the lesion to extend downward; the direction of the lesion depends on the patient's position as vessel

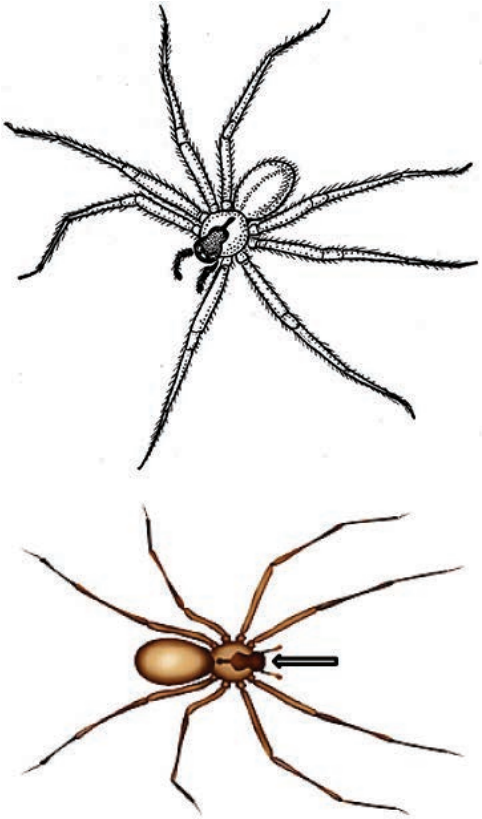
doi:10.1128/9781555819002.ch35.f53



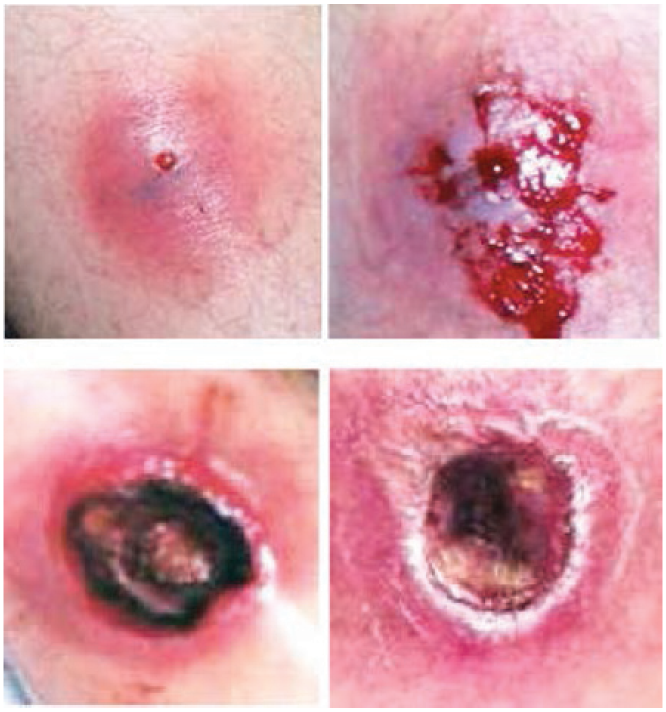


Figure 35.54 Tissue necrosis caused by *Loxosceles* sp. (brown recluse, violin spider); note the progression of the wound from day 1 to approximately the end of the year (upper left to lower right). doi:10.1128/9781555819002.ch35.f54

damage occurs. This bite presentation is apparently rare with other arthropod bites. Mild to severe pain can occur immediately after the bite or within a few hours. Extensive tissue necrosis can occur, with extended spread, very slow healing, and severe disfigurement (Fig. 35.54). If a large dose of venom is injected, there may also be systemic complications, such as hemolytic anemia, hemoglobinuria, hematuria, jaundice, and fever. There is a high mortality rate associated with systemic complications, which can include hematuria, anemia, fever, rash, nausea, vomiting, coma, and cyanosis. If systemic symptoms occur, they usually appear several days after the bite; as an example, hemolysis has been documented to occur from 24 h to 3 days after a bite.

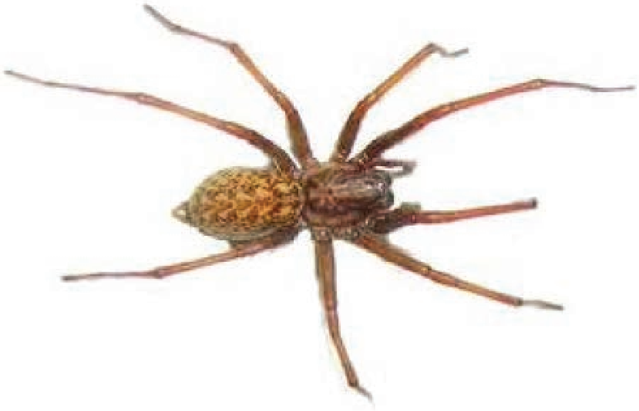
The brown recluse is nocturnal and is generally found in bathrooms, bedrooms, cellars, attics, clothing folds, boxes, storage areas, under rubble, etc. Like the black widow spider, it is not aggressive but will bite when bothered. As of 2011, the range of *L. reclusa* is centered in the United States, from Kansas east to Kentucky and from southern Iowa south to Louisiana. Newly influenced areas may include parts of Nebraska, Minnesota, Wisconsin, Michigan, South Dakota, Ohio, and Pennsylvania (77).

In South America, there is a close relative of the brown recluse, *Loxosceles laeta*, which also causes a severe necrotic lesion; these spiders have been introduced and are now well established in Los Angeles, CA, and at Harvard University in Cambridge, MA (6). Other species found mostly in the Southwest include *L. refescens*, *L. deserta*, *L. devia*, and *L. arizonica*.

As with any spider bite, if possible the spider should be collected and submitted for identification. In the case of the brown recluse, prompt medical attention is recommended. Although a specific antivenom has been used, it is not generally available. Treatment is somewhat controversial, ranging from ice packs to complete surgical excision of the bite site. Antibiotics such as cephalosporin or erythromycin have been used, as well as dapsone; however, the side effects of dapsone may also mimic symptoms resulting from the spider bite. Even in cases of verified spider bite, differentiation must be made between toxic effects of venom and secondary infections, such as incurred when pruritus leads to scratching. The medical community needs to be aware of the many causes of necrotic wounds that can be misdiagnosed as recluse bites. Culture of specimens taken from wounds might accurately determine the plethora of causative agents of so-called brown recluse bites, which can vary from being arthropod, bacterial, viral, or fungal in nature or due to underlying disease states.

Hobo Spiders. Hobo spiders are large, fast spiders, about 45 mm long with distinct chevron stripes on the abdomen. They are light to medium brown color, the thorax has two dark stripes and one inner light stripe, and the abdomen has a light stripe down the midline that is interrupted by light markings (Fig. 35.55). They build funnel-shaped webs in or around houses. They are also now recognized as causing necrotic lesions, particularly the males, which are responsible for most bites. Reports of bites in Washington, Oregon, and Idaho continue to increase. Although the bites were originally thought to be from brown recluse spiders,

Figure 35.55 Hobo spider, 45 mm long with distinct chevron stripes on the abdomen. doi:10.1128/9781555819002.ch35.f55



this was never confirmed. It appears that the bite of these hobo spiders can cause lesions similar to those seen with bites by the brown recluse. The species involved is *Tegenaria agrestis*. Although the bite is usually painless at first, the same types of lesions and symptoms occur as seen with bites by the brown recluse. Some of these lesions can take years to heal, and systemic symptoms can also be seen. The bite of the hobo spider usually is initially painless. Induration may appear within 30 minutes, surrounded by an area of expanding erythema that can attain a diameter of 5 to 15 cm. Blisters develop within 15 to 35 hours; the blisters can rupture with a serous exudate encrusting the cratered wound. An eschar can develop with underlying necrosis and eventual sloughing of affected tissue. Lesions normally heal within 45 days, but can result in a permanent scar; healing may take 3 years if the bite occurred in fatty tissue. The most common symptom is a severe headache, which occurs as soon as 30 minutes after the bite and usually within 10 hours, and can persist for a week. Other symptoms can include nausea, weakness, fatigue, temporary memory loss, and vision impairment. Protracted systemic effects, including aplastic anemia, intractable vomiting, or profuse secretory diarrhea, are rare but may be associated with death.

Funnel Web Spiders. Funnel web spiders are large, dark-colored, and very aggressive; they have prominent fangs and are found in and around Sydney, Australia. They are glossy dark brown to black, while the abdomen is dark plum to black; including the legs, they measure 45 to 60 mm (Fig. 35.56). They tend to build funnel webs in burrows, rotting logs, tree holes, or rock crevices; colonies can number more than 100 spiders. These are very dangerous spiders, and the bite can cause death in as little as 15 min. The bite can become very painful, and systemic symptoms such as hypotension and apnea can begin to occur within just a few minutes.

It is important for first aid to be administered immediately, including a pressure bandage and immobilization of the limb with splints. Patients are usually hospitalized and monitored for signs and symptoms indicating that venom has or has not been injected with the bite. These systemic symptoms can include mouth numbness, tongue spasms, nausea, vomiting, profuse sweating, salivation, and muscle spasms. Appropriate administration of antivenom is indicated; however, it is important to carefully monitor patients for possible allergic reactions to the antivenom.

Tarantula Spiders. Tarantulas occur throughout different areas of the world and become aggressive only if provoked or handled inappropriately. They are large, hairy spiders (Fig. 35.57). The 30 species found in the southwestern United States have a leg span of approximately 18 cm, while the South American species found in the jungles measure 24 cm. Bites can vary from being relatively painless to causing a deep, throbbing pain that may last for hours. Individuals who are hypersensitive may present with more serious symptoms. Tarantulas sold for pets within the United States are generally species of *Abhonopelma*, which tend to be very colorful. Bites by several genera of African, Asian, and Australasian tarantulas can cause

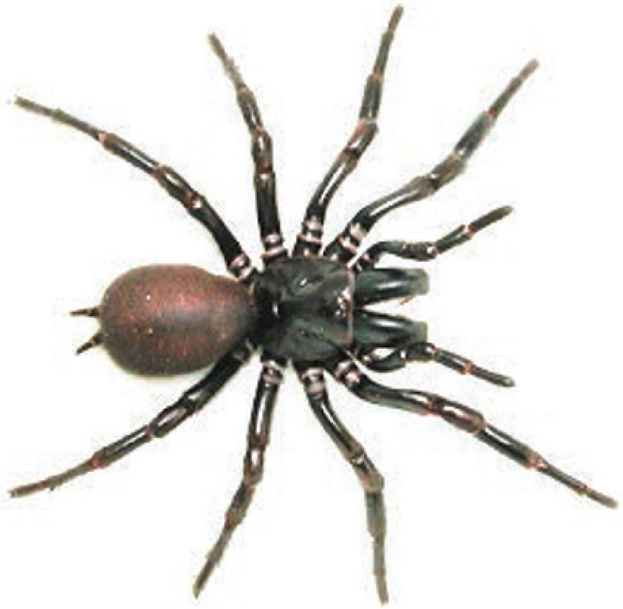


Figure 35.56 Funnel web spider, 45 to 60 mm, large, dark colored. (Courtesy of Museum Victoria, photographer Alan Henderson, www.museumvictoria.com.au.)
doi:10.1128/9781555819002.ch35.f56

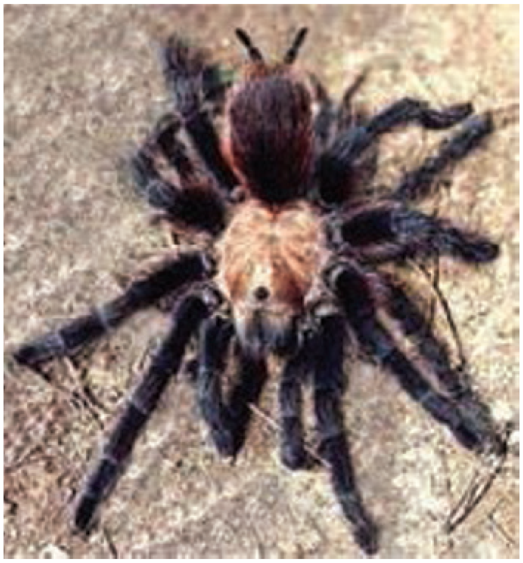
doi:10.1128/9781555819002.ch35.f57

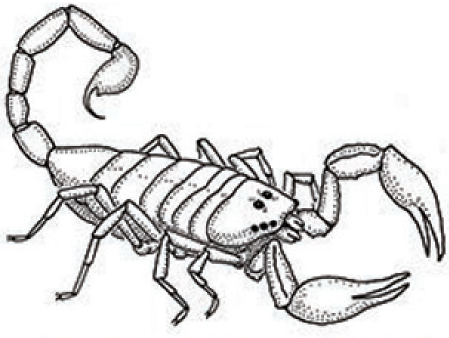


systemic neurotoxic envenoming. In the absence of available antivenom, severe persistent muscle spasms, reminiscent of latrodectism, pose a serious therapeutic challenge. New World tarantula bites appear to be clinically trivial with the possible exception of a few genera such as *Sericopelma* (*Theraphosinae*). However, Old World tarantulas, which lack protective urticating hairs, are more ready to bite and commonly cause local pain, swelling, and stiffness of the joints.

Subclass Scorpiones (Scorpions)

Scorpions are characterized by having large pedipalps that end in stout claws and a tail ending in a hooked stinger (Fig. 35.58). Venom is discharged through the stinger. Humans usually come into contact with scorpions by stepping on them or touching them in the dark. Species considered to be dangerous occur throughout the world. Some species can even penetrate the soles of the feet and inject venom, causing symptoms which can be serious, particularly in children younger than 5 years (aching pain radiating from the site; lymphadenitis; generalized numbness; throbbing and twitching of fingers, toes, and earlobes; profuse sweating; glossopharyngeal involvement; vomiting; abdominal muscle spasms; convulsions; mental disturbances; partial paralysis; blindness; electrocardiographic changes; and death from respiratory paralysis).

Figure 35.58 Scorpion. (Upper) 30 to 40 mm (illustration by Sharon Belkin). (Lower) Although painful, scorpion stings are rarely fatal. Exceptions are infants and children who sustain multiple stings. The venom is contained in two venom glands in the tail. (Courtesy of the U.S. Department of Agriculture.) doi:10.1128/9781555819002.ch35.f58



Children younger than 5 years are most commonly exposed and have the most severe sequelae. It has been reported that in Trinidad, the death rate in exposed children can reach 25% (9). Usually, the death rate in exposed adults is very low.

Scorpions are nocturnal and generally are hidden during the day. Around homes, they are often found under houses or in attics. When actively seeking water, they may be found in kitchens or bathrooms, occasionally in the sink or bathtub. In the southwestern United States, the common striped scorpion, *Centruroides vittatus*, is found; it has a sting similar to that from a wasp or bee. *C. vittatus* is found in Texas, while *Centruroides exilicauda* is found in southern Arizona and western New Mexico.

Most stings are not serious, and the burning sensation and wheal disappear without any intervention. However, after a sting by one of the more dangerous species, it is important to minimize the spread of the venom. Ice packs are recommended, and medical treatment may be required. Areas of the world where dangerously venomous scorpions are found include (Old World) Algeria, Egypt, Iraq, Israel, Jordan, Morocco, South Africa, Sudan, and Turkey and (New World) Argentina, Brazil, Guyana, Mexico, Trinidad, United States (Arizona and New Mexico), and Venezuela (6).

Scorpion envenomations are a major public health problem in Brazil, whose most dangerous cases are attributable to the genus *Tityus*; approximately 50,000 cases are reported annually. Symptoms frequently observed at the sting site were local and radiating pain, paresthesia, edema, erythema, sweating, piloerectio, and burning. The systemic manifestations were significantly higher in patients from the western part of Brazil. Furthermore, neurological symptoms such as general paresthesia, ataxia, dysarthria, myoclonus, dysmetria, and electric shock-like sensations throughout the body were reported only by patients from the west (78). The specific treatment for scorpion envenomations in Brazil is based on the administration of species-specific antivenom, obtained from plasma of horses immunized with the venoms of *T. serrulatus*, which has been used effectively for the treatment of human scorpionism attributable to *T. serrulatus* and other species such as *T. stigmurus* and *T. bahiensis*.

Other Arthropods

Class Chilopoda (Centipedes)

Centipedes are usually not considered dangerous, and their importance is related to their occasional painful bites. These arthropods like to live in dark, damp environments such as debris and rubbish. They have a long, slender,

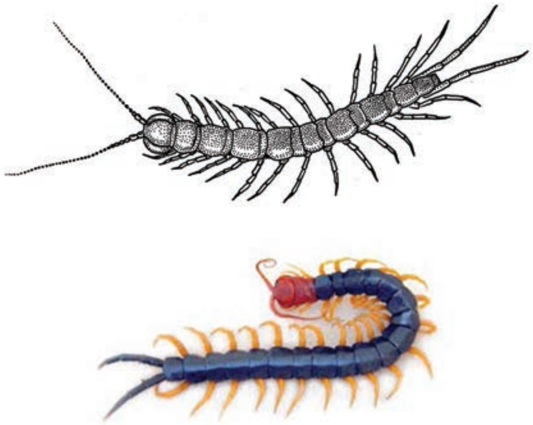


Figure 35.59 Centipede. (Upper) 30 to 40 mm; some may be much larger (illustration by Sharon Belkin).(Lower) *Scolopendra heros*. This is the largest-bodied centipede in North America, growing up to 7 inches or so. It ranges from Kansas and southern Missouri to Louisiana, westward through Texas and New Mexico/eastern Colorado to the Colorado River in Arizona, and southward about one-fourth of the way into Mexico. (Photograph courtesy of Seth Peterson, http://bugguide.net/node/view/50108.) doi:10.1128/9781555819002.ch35.f59

segmented body with a single pair of legs per segment except for the last two segments (Fig. 35.59) (6). The appendages of the first body segment are modified into poison claws. Although the poison injected is not harmful in the temperate areas of the world, the bite of *Scolopendra* spp. within the tropics and subtropics can be very painful and can cause edema, blistering, and necrotic lesions. In some cases, systemic reactions such as fever, nausea, vomiting, and headache also occur, particularly with *Scolopendra gigantea*. Rarely, some species have been recovered from the human nares and frontal sinuses or from the digestive tract; in each case, the centipede was an accidental invader of the human body (5).

Most bites are mild and self-limiting. The bite site should be thoroughly washed, with subsequent application of an ice pack and analgesics for pain. If the lesion becomes inflamed, antibiotics may be recommended.

Class Diplopoda (Millipedes)

Millipedes also have a long, slender, segmented body, but unlike the centipedes, they have two pairs of legs per segment in the abdominal region (Fig. 35.60). Also, they tend to be more round and “wormlike” in shape. They do not have piercing mouthparts, and they are not poisonous. However, some of the body secretions can result in a burning sensation, discoloration, and blister formation when applied to human skin. Severe conjunctivitis can also occur when the eyes come in contact with these fluids (55). Apparently, these secretions contain hydrogen cyanide as well as other aliphatic acids (9).

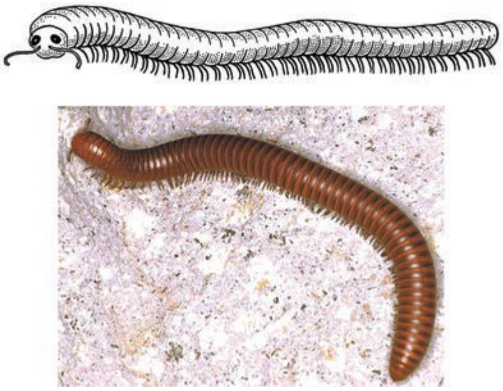

Figure 35.60 Millipede, 30 to 40 mm. (Upper, illustration by Sharon Belkin; lower, courtesy of the U.S. Department of Agriculture.) doi:10.1128/9781555819002.ch35.f60

Class Crustacea (Copepods, Crabs, Crayfish, etc.)

The crustaceans are primarily gill-breathing arthropods of both freshwater and saltwater. Only a few are of medical importance, and these tend to be found in freshwater. Some of the members of this group serve as intermediate hosts for various human helminth parasites. Copepods, or water fleas, serve as intermediate hosts for several helminth infections. Species of *Cyclops* carry the larval forms of *Dracunculus medinensis* (guinea worm), *Diphyllobothrium latum* (broad fish tapeworm), and *Gnathostoma spinigerum* (uncommon nematode infection). Species of *Diaptomus* are important first intermediate hosts of *D. latum*. Prevention of contamination and boiling or filtration of contaminated water will prevent these infections.

The larger crustaceans (decapods) include crabs and crayfish, which serve as the second intermediate hosts of *Paragonimus* spp. (lung fluke). Although the crabs incriminated in the transmission of *Paragonimus* spp. are freshwater forms, they can also survive in brackish water. Thorough cooking of crabs and crayfish will help eliminate some of these infections.

In the South Pacific, prawns may be paratenic hosts of the nematode *Angiostrongylus cantonensis*, which can cause eosinophilic meningitis and cerebral damage in the human host.

Control of Arthropods of Medical Importance

Measures for the control of medically important arthropods usually involve a number of different options, including physical control, biological control, and chemical control.

Although chemical means are generally the most widely used, they rarely succeed in providing a permanent solution to the problem. Often, a combination of methods provides the most effective control (79). A general dichotomous key for the identification of some of the arthropods can be found in Appendix 35.4, and a key to the important myiasis-producing larvae is provided in Appendix 35.5.

Physical Control

A number of control measures are related to the environment and may affect arthropod life cycles. An excellent example is demonstrated by the elimination of larval habitats of mosquitoes; this is basically water management. This approach could include rerouting of water, elimination of standing water, and ditch filling. With periodic monitoring, these should be long-term changes and should require little to no maintenance. Other approaches would include proper disposal of sewage, garbage, manure, and trash. Screens, bed nets, and protective clothing have become widely used and appreciated as preventive measures against flying insects. Although several other methods have been tried, they are somewhat questionable, at best. One example is the use of pet products such as flea collars. The use of flea collars for humans has not been approved by the Food and Drug Administration and may be dangerous due to the potential for pesticide absorption through the skin.

Biological Control

"Classical" biological control is based on the importation of exotic natural enemies (parasites, predators, or pathogens) and their long-term establishment in the new environment, a strategy which may then provide long-term control of the target exotic pest arthropod. Classical biological control has been actively practiced for about 100 years in the United States. Genetic manipulation of natural enemies of arthropods offers promise of enhancing their efficacy in agricultural cropping systems. A number of programs are currently being used and include (i) use of specific viruses, bacteria, protozoa, nematodes, and fungi, all of which are pathogenic for various arthropods; (ii) genetic manipulation of arthropod populations, including release of sterile males and use of insect growth regulators; and (iii) release of actual predators such as the small fish *Gambusia affinis*, which feeds on mosquito larvae. The introduction of the irradiation technique for sterilizing males of the screwworm fly, *Cochliomyia hominivorax*, has dramatically limited the development of progeny of this myiasis-producing fly throughout the southern United States. Chemosterilants are also being used, in some cases eliminating the need for radiation techniques. Insect growth regulators generally cause reproductive dysfunction or inhibit development of the adult stage. Specific vector control guidelines can be found in references 49, 80, 81.

Chemical Control

Although chemical control measures dramatically increased after World War II, the current approach involves combination methods rather than relying on chemical means alone. Concerns have been raised about a number of chemicals, particularly in terms of their possible contamination of the food chain. Also, different chemicals and approaches vary considerably throughout the world, often depending on location and financial considerations.

Most insecticides currently in use include inorganic compounds (arsenicals and fluorine compounds), botanicals (pyrethrins from pyrethrum flowers), chlorinated hydrocarbons (DDT, lindane, chlordane, dieldrin, and methoxychlor), and organophosphorus (malathion, dicapthon, and parathion) and carbamate (Baygon, Sevin, and Bendiocarb) compounds. A great deal of emphasis has been placed on the residual action of certain insecticides, compounds that remain stable on surfaces for long periods but which are effective at very low concentrations. These residual sprays are quite different from those that are sprayed ("space sprayed") for short-term effectiveness.

Unfortunately, as with all animal populations, susceptibility and resistance to these insecticides will vary; arthropods that are resistant will survive. Cross-breeding of these survivors often tends to enhance the resistance. This has occurred with insects exposed to chlorinated hydrocarbons and organophosphorus compounds.

Insecticides can be applied as sprays (immediate action or residual), aerosols (the insecticide remains suspended in air for a long time), ultra-low-volume concentrates (essentially no solvents are used), dusts (10% insecticide in talc or pyrophyllite inert carriers), granules (inorganic carrier such as vermiculite), or bait (houseflies, cockroaches, ants). Repellents and acaricides can also be used for those who are exposed to arthropods in infested areas. True repellents do not kill the arthropods but discourage them from landing or biting.

Appendix 35.1 Medically important arthropods and their potential effect on humans

Representative species	Common name	Geographic distribution	Effect(s) on humans
Insecta			
Anoplura (sucking lice)			
Pediculus humanus humanus	Body louse	Worldwide	Skin reactions to bites; vectors of rickettsiae and spirochetes
P. humanus capitis	Head louse	Worldwide	Skin reaction to bites
Phthirus pubis	Crab louse	Worldwide	Skin reaction to bites
Mallophaga (biting lice)			
Trichodectes canis	Dog louse	Worldwide	None—can transmit *Dipylidium caninum*
Hemiptera (true bugs)			
Cimex lectularius	Bedbug	Worldwide	Skin reaction to bites
C. hemipterus	Tropical bedbug	Tropical and subtropical	Skin reaction to bites
Triatoma infestans, *Rhodnius prolixus*, *Panstrongylus megistus*	Kissing bug, conenose bug	Tropical and subtropical regions of the New World	Skin reaction to bites; vectors of *Trypanosoma cruzi*, the cause of Chagas' disease
Hymenoptera (bees, wasps, ants)			
Apis mellifera	Honeybee	Worldwide	Painful sting, potential anaphylaxis
Bombus spp.	Bumblebee	Worldwide	Painful sting, potential anaphylaxis
Various genera and species of the family Vespidae	Wasp, hornets, yellow jackets	Worldwide	Painful sting, potential anaphylaxis
Solenopsis spp.	Fire ant	Tropical America, southeastern and southwestern United States	Painful bite and multiple stings, potential anaphylaxis
Diptera (flies, mosquitoes, and their relatives)			
Culicoides spp./*Leptoconops* spp.	Biting midge	Worldwide	Serious biting pest; skin reaction to bites; vectors of several filarid nematodes
Phlebotomus spp./ *Lutzomyia* spp.	Sand fly	Worldwide/tropical region of New World	Skin reaction to bites; vectors of leishmanias, bacteria, and viruses
Simulium spp.	Blackfly, buffalo gnat	Worldwide	Serious biting pests; skin reaction to bites; vectors of *Onchocerca* and *Mansonella* spp.
Aedes spp.	Mosquito	Worldwide	Serious biting pests; skin reaction to bites; vectors of viruses, protozoa, and filaria
Anopheles spp.	Mosquito		
Culex spp.	Mosquito		
Culiseta spp.	Mosquito		
Mansonia spp.	Mosquito		
Tabanus spp.	Horsefly	Worldwide	Biting pests; painful bite followed by skin reaction
Chrysops spp.	Deerfly	Worldwide	Biting pests; vectors of tularemia and *Loa loa*
Glossina spp.	Tsetse fly	Africa	Biting pests; vectors of African trypanosomes
Siphonaptera (fleas)			
Ctenocephalides canis, *C. felis*	Dog flea, cat flea	Worldwide	None—can transmit *Dipylidium caninum*
Pulex irritans	Flea	Worldwide	Dermatitis, ulcerations
Xenopsylla cheopis	Rat flea	Worldwide	None—can transmit *Hymenolepis diminuta*
Tunga penetrans	Chigoe flea	Tropical and subtropical	Nodular swelling with subsequent ulceration

(continued)

Appendix 35.1 Medically important arthropods and their potential effect on humans *(continued)*

Representative species	Common name	Geographic distribution	Effect(s) on humans
Orthoptera (cockroaches, grasshoppers, and their relatives)			
Blatella germanica	German cockroach	Worldwide	Mechanical disseminator of pathogens; intermediate host of certain helminths
Periplaneta americana	American cockroach	Worldwide	
Various genera	Cockroach	Worldwide	
Coleoptera (beetles)			
Various genera and species	Beetles	Worldwide	Mechanical disseminators of pathogens
Various species of the family *Meloidae*	Blister beetles	Worldwide	Blistering of skin after contact with adult
Tenebrio spp.	Grain beetles	Worldwide	Intermediate hosts of tapeworms—*Hymenolepis* spp.
Lepidoptera (moths and butterflies)			
Various genera and species	Caterpillar	Worldwide	Urticating spines and hairs may cause reaction when handled or inhaled
Arachnida			
Scorpionida (scorpions)			
Various genera and species	Scorpion	Tropical and subtropical	Initially painful sting, often followed by systemic reactions
Araneidae (spiders)			
Lactrodectus mactans	Black widow spider	Americas	Bite usually painless, delayed systemic reaction
Lactrodectus spp.	Widow spider	Worldwide	Bite usually painless, delayed systemic reaction
Loxosceles reclusa	Brown recluse spider	Americas	Initial blister at wound site followed by sometimes extensive necrosis and slow healing
Loxosceles laeta	South American brown spider	South America	
Acarina (ticks and mites)			
Ornithodoros spp.	Soft tick	Worldwide	Skin reactions to bite; tick paralysis; vectors of relapsing fever
Amblyomma spp.	Hard tick	Worldwide	Skin reactions to bite; tick paralysis; vectors of rickettsias, viruses, bacteria, and protozoa
Dermacentor spp.			
Ixodes spp.			
Demodex folliculorum	Follicle mite	Worldwide	Found in sebaceous glands and hair follicles, occasional skin reactions
Sarcoptes scabiei	Human itch mite	Worldwide	Burrows in skin, causing severe itching
Trombicula spp.	Chigger, red bug	Worldwide	Intense itching at site of attachment; vectors of rickettsias
Crustacea			
Cyclops spp.	Copepod	Worldwide	Intermediate hosts of guinea worm and broadfish tapeworm
Diaptomus spp.			
Chilopoda			
Scolopendra spp.	Centipede	Tropical and subtropical	Painful bite
Pentastomida			
Linguatula serrata	Tongue worm	Tropical	Endoparasitic in internal organs

Appendix 35.2 Common arthropods: diagnostic procedures and recommended therapy

Name	Symptoms	Diagnostic procedure	Recommended therapy
Fly larvae			
Cutaneous, mucocutaneous	Painful, indolent ulcers; furuncle-like sores; dermal lesions like creeping eruption	Remove larvae, place in petri dish (blood agar plate). Identification will depend on examination of the larval stigmal plates and/or the adult fly (should often be referred to an experienced entomologist).	Local palliatives, often including antibiotics for secondary infections
Nose	Obstruction of nasal passages, facial edema, and fever		
Ear	Crawling sensations, buzzing noises, foul-smelling discharge		
Eye	Severe irritation and pain		
Intestinal	Severe nervous symptoms as well as internal irritation		Treatment with castor oil will expel these larvae
Bedbugs	Asymptomatic, edema, inflammation, indurated ring at site of feeding, asthma, anxious concern	Examination and identification of adult bug	Local palliatives and insecticides, thorough washing of all bedding
Reduviid bugs (kissing bugs, conenose bugs)	Local swelling and induration, oozing of blood from puncture site, generalized urticaria (bites commonly on exposed parts of skin, face, outer area of eye, lip)	Examination and identification of adult bug	Local palliatives
Fleas			
Tunga penetrans	Adult female burrows into skin (often toes and feet), causing nodular swelling, subsequent ulceration and festering sores	Examination and identification of adult flea	Wearing shoes, flea removal aseptically with needle, bathing of wound and treating with antiseptic
Pulex irritans (human), *Xenopsylla cheopis* (rat), *Ctenocephalides canis* (dog)	Asymptomatic; roseate raised lesion, frequently edematous, indurated, or pustular (bites are more common on lower extremities)		Local palliatives, use of recommended insecticides
Lice			
Pediculus spp., *Phthirus pubis*	Cutaneous lesions, roseate elevated papule, intense pruritus, lesions may become secondarily infected by bacteria	Examination and identification of adult and/or eggs on hair shaft	Shampoo or ointment (1% lindane); dusts with 1% malathion; bedding can be fumigated with ethyl formate; remaining nits can be removed with fine-toothed comb
Ticks			
Tick paralysis	Generalized toxemia, fever (104°F), rapid ascending flaccid paralysis, difficulty in swallowing and respiration, and death; little or no change in white cell count	Careful examination of body, particularly back of the neck and along spinal column	Prompt removal of the engorging female tick will usually limit progression of paralysis (due to toxin in tick saliva)
Other ticks and bites	Inflammatory infiltration of tissues, local hyperemia, edema, hemorrhage (histolysis at the bite site as a result of salivary secretions)	Examination and identification of adult tick	Anterior portion should be grasped with forceps close to the skin and pulled *straight out*; leaving mouth parts may cause severe tissue reactions and possible secondary infections

(continued)

Appendix 35.2 Common arthropods: diagnostic procedures and recommended therapy *(continued)*

Representative species	Common name	Geographic distribution	Effect(s) on humans
Mites			
Sarcoptes scabiei (itch mite)	Small skin vesicles; scratching results in bleeding and scab formation followed by secondary infection	Skin scraping (avoid excoriated lesions); get material from early papule or burrow (between fingers, wrists, elbows, axillae, penis, scrotum, buttocks, backs of knees, ankles, toes, under breasts)	Topical application of 1% lindane in lotion or ointment (may require one to three applications); should be applied after scrubbing and soaking in warm water to expose lesions
Spiders			
Black widow spider	Symptoms will depend on amount of venom injected; may include abdominal cramps, hypertension, and convulsions	History and/or identification of spider	Specific antivenom is available (patients should be tested for horse serum sensitivity before use); other supportive therapy depending on symptoms
Violin spider, brown recluse spider	Bite may be painless; mild to severe pain within hours; erythema, vesicle formation, and itching followed by chills, headache, and nausea; the lesion becomes necrotic, spreads, and heals very slowly; kidney damage and death may also occur	Identification of spider	Prompt administration of steroids, early surgical excision of lesion (skin grafting may be necessary), treatment of secondary infections

Appendix 35.3 Common terms used in discussing arthropods

Term	Definition
Antennae	Segmented appendages located in the lateral side of the head
Capitulum	"False head" found in arachnids; basal portion of structure is "basis capituli"
Cell	Area of wing enclosed by veins
Cerci	Appendages (slender, two) at terminal abdominal segment
Chelicerae	Appendages (grasping or cutting) in place of jaws; found in arachnids
Claw	Appendage (sharp, curved) at end of leg
Complete metamorphosis.	Cycle of development (e.g., egg, larva, pupa, adult); each stage distinct from others
Compound eye	Visual elements (large number) grouped on each side of head
Costa	Thickening of the anterior edge of the wing
Coxa	Proximal segment of the leg
Ecdysis	Shedding of larval skin during transformation from one stage to another
Emergence	Appearance of winged insect from the pupal stage
Epipharynx	Organ attached to inner part of labrum
Exoskeleton	External skeleton
Fat body	Group of cells (widely distributed, food store); contains protein, fats, glycogen
Festoons	Notches seen at posterior part of body of hard ticks
Gill	Specialized respiratory organ seen in aquatic insects
Haltere	Club-shaped structure in place of second pair of wings in Diptera
Hypopharynx	Tongue-shaped structure; lies between labrum and labium; connected to salivary duct
Hypostome	Lower lip which takes the form of an elongated structure armed with teeth or hooks in ticks
Incomplete metamorphosis	Morphology between adults and immature stages similar; stages resemble each other
Labial palpi	Pair of appendages arising from each side of the labrum
Labium	Lower lip which forms floor of mouth
Labrum	Upper lip which forms roof of the mouth
Longitudinal veins	Series of six veins following the subcosta; numbered in sequence
Maggot	Common name given to larva of some Diptera (flies)
Mandibles	Pair of upper jaws
Maxillae	Pair of lower jaws
Mesonotum	Dorsal surface of second thoracic segment
Myiasis	Infestation of human and animal tissues with fly maggots
Nymph	Immature stage in insects undergoing incomplete metamorphosis
Ocellus	Simple eye
Ovipositor	Tubular structure through which eggs are laid
Palmate hairs	Fan-shaped hairs on dorsal surface of anopheline larva
Pedipalp	Second pair of appendages which arise from cephalothorax in arachnids
Pleuron	Lateral part of a segment
Pronotal comb	Anterior segment of thorax
Pronotum	Dorsal surface of first thoracic segment
Prothorax	Anterior segment of thorax
Pseudotracheae	Small tubes found on labella (through which fluid is sucked) in houseflies and members of the *Tabanidae*
Pygidium	Pincushion-like structure seen on ninth segment of fleas
Scutellum	Small posterior section of the tergum
Scutum	Chitinous shield seen on the dorsum of Acarina
Sensilla	Hairs which have sensory function
Setae	Hairlike structures which are hollow internally
Spermatheca	Sperm-storing organ in lower genital tract of females
Spiracles	Respiratory openings
Subcosta	Vein lying posterior to the costa
Tergum	Dorsal plate on thoracic segment
Tissue invasion	Infestation (superficial tissues); infection (deeper tissues)
Tracheae	Ringed breathing tubes
Vector	Transmitter of infection (arthropods)

Appendix 35.4 Dichotomous key to some of the arthropods important in human disease and/or disease transmission

A.	Legs:	Three or four pairs	B
	Legs:	Five or more pairs	V
B.	Legs:	Three pairs; antennae present	C
	Legs:	Four pairs; antennae absent	L
C.	Wings:	Well developed	D
	Wings:	Absent or rudimentary	L
D.	Wings:	One pair (**Diptera**: flies, mosquitoes, midges)	E
	Wings:	Two pairs	F
E.	Wings:	Scales present (**Diptera**: mosquitoes)	
	Wings:	Scales absent (**Diptera**: flies)	
F.	Mouth parts:	Sucking (long proboscis present)	G
	Mouth parts:	Chewing (long proboscis absent)	H
G.	Wings:	Scales present; proboscis coiled (**Lepidoptera**: butterflies, moths)	
	Wings:	Scales absent; proboscis not coiled (**Hemiptera**: bedbugs, kissing bugs)	
H.	Wings:	Both pairs membranous, size may vary	I
	Wings:	Front pair leathery or shell-like, covers second pair	J
I.	Wings:	Both pairs similar in size (**Isoptera**: termites)	
	Wings:	Hind wing smaller than front wing (**Hymenoptera**: bees, hornets, wasps)	
J.	Wings:	No distinct veins; front wings horny or leathery; meet as straight line in middle	K
	Wings:	Distinct veins; front wings horny or leathery; overlap in middle (**Blattaria**: cockroaches)	
K.	Abdomen:	Prominent cerci or forceps, longer than wings (**Dermaptera**: earwigs)	
	Abdomen:	No prominent cerci or forceps, covered by wings (**Coleoptera**: beetles)	
L.	Abdomen:	Three long terminal tails (**Thysanura**: silverfish and firebrats)	
	Abdomen:	No terminal tails	M
M.	Abdomen:	Narrow waist (**Hymenoptera**: ants)	
	Abdomen:	No narrow waist	N
N.	Abdomen:	Prominent pair of cerci or forceps (**Dermaptera**: earwigs) (see also K)	
	Abdomen:	No cerci or forceps	O
O.	Body:	Flattened laterally; antennae folded into head grooves (**Siphonaptera**: fleas)	
	Body:	Flattened dorsoventrally; antennae project from side of head	P
P.	Antennae:	Nine or more segments	Q
	Antennae:	Three to five segments	R
Q.	Pronotum:	Covers head (**Blattaria**: cockroaches) (see also J)	
	Pronotum:	Does not cover head (**Isoptera**: termites) (see also I)	
R.	Mouth parts:	Tubular jointed beak; three- to five-segmented tarsi (**Hemiptera**: bedbugs)	
	Mouth parts:	Retracted into head or chewing type; one- or two-segmented tarsi	S
S.	Mouth parts:	Retracted into head, adapted for sucking blood (**Anoplura**: sucking lice)	
	Mouth parts:	Chewing type (**Mallophaga**: chewing lice)	

(continued)

Appendix 35.4 *(continued)*

T.	Body:	Oval, consisting of a single saclike region (**Acari**: ticks and mites)	
	Body:	Divided into two distinct regions, cephalothorax and abdomen	U
U.	Abdomen:	Joined to cephalothorax by slender waist (**Araneae**: spiders)	
	Abdomen:	Joined broadly to cephalothorax, stinger present (**Scorpiones**: scorpions)	
V.	Legs, swimmerets:	Five to nine pairs of legs or swimmerets; one or two pairs of antennae (**Crustacea**: copepods, crabs, crayfish)	
	Legs, swimmerets:	Ten or more pairs of legs; swimmerets absent, one pair of antennae	W
W.	Legs per body segment:	One pair (**Chilopoda**: centipedes)	
	Legs per body segment:	Two pairs (**Diplopoda**: millipedes)	

[a] Adapted from references 1–9, 55.

Appendix 35.5 Key to the important myiasis-producing larvae[a]

1.	Body with spinous or fleshy processes laterally and dorsally or terminally	*Fannia*
	Body smooth or with short spines, but *never* having long fleshy lateral processes	2
2.	Body with a long slender tail or caudal process capable of some extension and retraction	*Eristalis*
	Body sometimes narrowed posteriorly, but *never* with a long flexible caudal process capable of some extension and retraction	3
3.	Larvae more or less grub-like; most species slightly flattened dorsoventrally	4
	Larvae maggot-like, or typical "muscoid" shape, tapering anteriorly, broadly truncate at the posterior end; cross section more or less circular at all points	5
4.	Posterior spiracular plate with three distinct slits	*Dermatobia*
	Posterior spiracular plate with many fine openings	*Hypoderma*
5.	Posterior spiracles within a well-chitinized and complete ring encircling the button area; spiracles *never* in a distinct depression	6
	Posterior spiracles with the button very slightly chitinized or absent; chitinized ring incomplete; spiracles in a distinct depression or flush with surface	8
6.	Button area with spiracular slits nearly straight	7
	Button area with spiracular slits sinuous, with at least a double curve	9
7.	Principal transverse subdivisions of spiracular slits well marked, usually not more than six; both ring and button heavily chitinized, the ring thickened into points at two places between the slits	*Calliphora*
	Transverse subdivisions of spiracular slits less distinctly marked, from 6 to 20 in number, ring and button less heavily chitinized, the ring thickened into point at only one place between the slits	*Phaenicia*
8.	Posterior spiracles in a more or less distinct pit or depression, vestigial button usually present; integument rather smooth	*Sarcophaga*
	Posterior spiracles flush with surface; integument rather spiny (Western Hemisphere)	*Cochliomyia*
9.	Posterior spiracular plates D-shaped, each slit thrown into several loops	*Musca*
	Posterior spiracular plates triangular, with rounded corners; spiracular slits S-shaped; button indistinct, centrally placed	*Stomoxys*

36

Treatment of Parasitic Infections

Chemotherapy plays a very important role not only in reducing patient morbidity and mortality but also in reducing transmission of the parasitic infection. Many of the drugs used to treat parasitic infections have serious side effects; therefore, before initiation of therapy, it is important to consider the following factors: health of the patient, parasite drug resistance, accuracy of the original dose, potential drug toxicity, and the need for follow-up examinations to monitor therapy. The mechanisms of action of most antiparasitic drugs are not well known, including those involving potential drug toxicity to the patient. Because of the limited resources of developing nations, where a majority of parasitic infections occur, there is little commercial incentive for developing effective therapeutics or vaccines. For some drugs, such as triclabendazole, used extensively in veterinary practices, less is known about adverse side effects or toxicity to humans. Specific information can be obtained from the Centers for Disease Control and Prevention, CDC Drug Service, Atlanta, GA (day, 404-639-3670; evenings, weekends, and holidays, 404-639-2888). One can also obtain drugs from CDC that are not commercially available in the United States.

Tables 36.1 and 36.2 provide information on the most commonly used drugs for treating parasitic infections; not all drugs are included, and some drugs listed are not available in the United States. In Table 36.1, unless specifically provided, pediatric doses are the same as that given for adults. Also, throughout the total literature, there may be some variations among the drug of choice and alternative options for the various parasitic infections listed in Table 36.1. References 1 to 3 contain overall drug information, while references 4 to 51 are very recent and cover almost all human parasitic infections. As an example, they begin with free-living amebae and end with trypanosomiasis.

Albendazole (Albenza) (Amedra)

Preparation

The drug is available as 200-mg tablets and is used for the treatment of *Ancylostoma caninum* (eosinophilic enterocolitis), anisakiasis, ascariasis, baylisascariasis, capillariasis, clonorchiasis, cutaneous larva migrans, hookworm, neurocysticercosis and hydatid disease, enterobiasis, loiasis, microsporidiosis, opisthorchiasis, strongyloidiasis, visceral larva migrans, and trichuriasis.

doi:10.1128/9781555819002.ch36

Administration

The drug is given with meals. It is poorly absorbed from the gastrointestinal tract due to its low aqueous solubility. Concentrations in plasma are negligible or undetectable because it is rapidly converted to the sulfoxide metabolite prior to reaching the systemic circulation. The systemic anthelmintic activity has been attributed to the primary metabolite, albendazole sulfoxide. Oral bioavailability appears to be enhanced when albendazole is coadministered with a fatty meal (estimated fat content, 40 g) as evidenced by higher (up to 5-fold on average) concentrations of albendazole sulfoxide in plasma compared to the concentration in plasma in fasted state.

Toxicity

Side effects include headache, vomiting, diarrhea, abdominal pain, increase in serum glutamic-oxaloacetic transaminase levels, and fever; migration of *Ascaris* through the mouth and nose may be seen.

Rare fatalities associated with the use of albendazole, due to granulocytopenia or pancytopenia, have been reported. Blood counts should be monitored at the beginning of each 28-day cycle of therapy and every 2 weeks during therapy with albendazole. Albendazole therapy may be continued if the total white blood cell count and absolute neutrophil count decrease appear modest and do not progress. Albendazole should not be used in pregnant women except in clinical circumstances where no alternative management is appropriate. Patients should not become pregnant for at least 1 month following cessation of albendazole therapy. If a patient becomes pregnant while taking this drug, the therapy should be discontinued immediately; the patient should be apprised of the potential hazard to the fetus.

Patients being treated for neurocysticercosis should receive appropriate steroid and anticonvulsant therapy as required. Oral or intravenous corticosteroids should be considered to prevent cerebral hypertensive episodes during the first week of anticysticercal therapy. Cysticercosis may, in rare cases, involve the retina. Before initiation of therapy for neurocysticercosis, the patient should be examined for the presence of retinal lesions. If such lesions are visualized, the need for anticysticercal therapy should be weighed against the possibility of retinal damage caused by albendazole-induced changes to the retinal lesion.

Contraindications

Due to lack of safety information, albendazole should not be given during pregnancy or lactation. Blood counts and liver function tests should be performed at the beginning of each 28-day treatment cycle and every 2 weeks.

Amphotericin B (AmBisome) (Gilead)

Preparation

The drug is supplied in vials containing 50 mg of amphotericin B inserted into a liposomal membrane and is used to treat mucocutaneous and visceral leishmaniasis and primary amebic meningoencephalitis. The product is lyophilized, and following reconstitution with sterile water, the pH is 5.0 to 6.0. It should be stored in the refrigerator and protected from light. It may be reconstituted with the addition of 12 ml of sterile water for injection USP, without a bacteriostatic agent, to make a 4-mg/ml solution. This may be further diluted by adding 1 ml of the 4-mg/ml solution to 40 ml of 5% glucose solution to make a final concentration of 0.1 mg of amphotericin per ml. The reconstituted product concentrate may be stored for up to 24 h under refrigeration. Injection of AmBisome should begin within 6 h of dilution with 5% dextrose injection. An existing intravenous line must be flushed with 5% dextrose injection prior to infusion of AmBisome. If this is not feasible, AmBisome should be administered through a separate line. AmBisome should never be reconstituted with saline, and saline must not be added to the reconstituted mixture. The mixture must not be mixed with any other drugs; this may cause precipitation of AmBisome.

Administration

AmBisome should be administered intravenously (i.v.), using a controlled infusion device, over a period of approximately 120 min. The infusion time may be reduced to approximately 60 min in patients in whom the treatment is well tolerated.

Toxicity

AmBisome-treated pediatric patients had a lower incidence of infusion-related fever, chills or rigors, and vomiting on day 1 than did amphotericin B deoxycholate-treated patients. The incidence of infusion-related cardiorespiratory events was also lower when AmBisome was used. In adult patients, AmBisome treatment resulted in a lower incidence of chills, hypertension, hypotension, tachycardia, hypoxia, hypokalemia, and various events related to decreased kidney function compared with amphotericin B deoxycholate.

Contraindications

AmBisome is contraindicated in patients who have demonstrated or have known hypersensitivity to amphotericin B deoxycholate or any other constituents of the product unless, in the opinion of the treating physician, the benefit of therapy outweighs the risk.

(continued on p. 1153)

TABLE 36.1 Drugs and dosages for treating parasitic infections[a]

Organism or infection	Drug	Dosage[b]	Follow-up[b] and comments
Acanthamoeba spp. Granulomatous amebic encephalitis	Pentamidine Sulfadiazine Flucytosine	4 mg/kg i.v. once/day 1.5 g every 6 h PO 37.5 mg/kg PO every 6 h (max 150 mg/kg/day)	Monitor clinical course; usually susceptible *in vitro* to pentamidine; addition of pentamidine based on clinical judgment
	Fluconazole	12 mg/kg i.v. once/day	Consult with CDC
	Miltefosine	Available from CDC	
Keratitis	Polyhexamethylene biguanide (Baquacil) (PHMB) or 0.2% chlorhexidine	0.02% applied topically hourly or every half hour for 3 days, then every 4 h	Monitor clinical course; combination therapy highly recommended; PHMB available at Leiter's Park Ave. Pharmacy, San Jose, CA (800-292-6773) (www.leiterrx.com) Prolonged therapy (≥6 mo) may be necessary
	plus/or		
	Propamidine isethionate (Brolene)	0.1% applied topically	
	plus		
	Neomycin-polymyxin B-gramicidin	Ophthalmic solution	Since most cysts are resistant to neomycin, this approach is no longer recommended.
Ancylostoma caninum (eosinophilic enterocolitis)	Drugs of choice: Albendazole	400 mg PO once	Monitor clinical course; endoscopic removal an option
	or		
	Mebendazole	100 mg PO BID × 3 days or 500 mg once	
Ancylostoma duodenale *Necator americanus* (hookworm)	Drugs of choice: Albendazole	400 mg PO once	Fecal examinations 2–4 wk posttherapy
	or		
	Mebendazole	100 mg PO BID × 3 days or 500 mg once	
	or		
	Pyrantel pamoate	11 mg/kg (max 1 g) × 3 days	If eggs are rare in fecal concentrations, there is no need to repeat therapy
Angiostrongylus cantonensis	Mebendazole	100 mg BID × 5 days	Monitor clinical course; may want to add corticosteroid; shorten course of infection
Angiostrongylus costaricensis	Drug of choice: Mebendazole	[pa200–400 mg TID × 10 days	Monitor clinical course; may want to add corticosteroid; shorten course of infection
	Alternative: Thiabendazole	75 mg/kg/day in 3 doses × 3 days (max 3 g/day)	
Anisakis spp.	Surgical or endoscopic removal Albendazole	400 mg PO BID × 3–5 days	Monitor clinical course; albendazole has also been reported to be successful

Ascaris lumbricoides (roundworm)	Drugs of choice:		
	Albendazole	400 mg PO once	Fecal examinations 2–4 wk posttherapy; nitazoxanide may be effective against a number of protozoa and helminths; available as 500-mg tablets and oral suspension—take with food
	or		
	Mebendazole	100 mg BID × 3 days or 500 mg once	
	or		
	Ivermectin	150–200 μg/kg PO once	
Babesia spp.	Drugs of choice:		
	Atovaquone plus	750 mg PO BID × 7–10 days Children: 40 mg/kg/day PO in 2 doses × 7–10 days	Monitor clinical course; repeat blood films if symptoms persist; concurrent babesiosis, Lyme disease and/or human granulocytic anaplasmosis may occur; atovaquone available in oral suspension—take with meal to increase absorption
	Azithromycin	500–1,000 mg PO on day 1, then 250–500 mg PO on days 2–10 Children: 10 mg/kg (max 500 mg/dose) PO on day 1, then 5 mg/kg/day (max 250 mg dose) PO on days 2–10	
	or		
	Clindamycin	300–600 mg i.v. QID or 600 mg PO TID × 7–10 days Children: 20–40 mg/kg/day (max 600 mg/dose) i.v. or PO in 3 to 4 doses × 7–10 days	Take with full glass of water to minimize esophageal ulceration
	plus		
	Quinine	650 mg PO TID or QID × 7–10 days Children: 24 mg/kg/day (max 600 mg/dose) PO in 3 doses × 7–10 days	
Balamuthia mandrillaris (granulomatous amebic encephalitis)	Azithromycin	500 mg i.v. once/day Children: 20 mg/kg i.v. once/day (max 500 mg/day)	Monitor clinical response and organisms in CSF; direct wet mounts of CSF and cultures Pentamidine can also be added based on clinical judgment
	Alternatives:		
	Clarithromycin (Biaxin)	14 mg/kg/day PO in 2 doses (max 2 g/day)	These 4 drugs used in combination
	Pentamidine	4 mg/kg i.v. once/day	
	Sulfadiazine	1.5 g PO every 6 h Children: 200 mg/kg/day PO in 4–6 doses (max 6 g/day)	
	Flucytosine (Ancobon)	37.5 mg/kg PO every 6 h (max 150 mg/kg/day)	
	Fluconazole	12 mg/kg i.v. once/day	
Balantidium coli	Drug of choice: Tetracycline	500 mg PO QID × 10 days Children (≥8 yr): 40 mg/kg/day in 4 doses × 10 days (max 2 g/day) PO	At least 3 negative fecal examinations 1 mo after therapy; contraindicated in pregnancy and in children <8 yr; take 1 h before or 2 h after meals and/or dairy products

(continued)

TABLE 36.1 Drugs and dosages for treating parasitic infections[a] *(continued)*

Organism or infection	Drug	Dosage[b]	Follow-up[b] and comments
	Alternatives:		
	Iodoquinol	650 mg PO TID × 20 days Children: 40 mg/kg/day (max 2 g/day) in 3 doses × 20 days	
	or		
	Metronidazole	500–750 mg PO TID × 5 days Children: 35–50 mg/kg/day PO in 3 doses × 5 days	
Baylisascaris procyonis (severe visceral and neural larva migrans) (raccoon roundworm)	Drugs of choice: Albendazole (mebendazole, thiabendazole, levamisole, ivermectin can be used if albendazole not available)	Check with CDC Drug Service Therapy must be started as soon as possible (up to 3 days after possible infection) Albendazole 37 mg/kg/day PO × 20 days combined with high-dose steroids	Steroids may also be helpful in eye and CNS infections; laser photocoagulation therapy has been used to destroy larvae in the retina; albendazole plus steroids recommended for children with known exposure
Blastocystis spp. (may comprise multiple strains, some pathogenic and some nonpathogenic)	Metronidazole	750 mg PO TID × 10 days Children: 35–50 mg/kg/day in 3 doses × 10 days	May see resistance with metronidazole; also may be reinfection; most common protozoan found in GI tract throughout the world (more common than *Giardia* or *Dientamoeba*)
	Trimethoprim/sulfamethoxazole	1 DS tab PO BID × 7 days	
	Iodoquinol	650 mg PO TID × 20 days Children: 30–40 mg/kg/day in 3 doses × 20 days	Fecal examinations 2 wk to 1 mo after therapy (must include permanent stain); metronidazole resistance may be common; another alternative would be TMP/SMX or nitazoxanide in children
Brugia malayi *Brugia timori*	Drug of choice: Diethylcarbamazine (available from CDC)	6 mg/kg/day PO in 3 doses × 1 or 12 days	Blood smears, Knott concentration, and membrane filtration of blood for microfilariae 2–4 wk after treatment; for patients with no microfilariae in the blood, full doses can be given from day 1 (6 mg/kg/day PO in 3 doses × 1 or 12 days)
Capillaria philippinensis	Drug of choice: Mebendazole	200 mg PO BID × 20 days	Multiple fecal examinations for eggs several months after completion of therapy
	Alternative: Albendazole	400 mg PO BID × 10 days	
Clonorchis (*Opisthorchis*) *sinensis* (Chinese liver fluke)	Drugs of choice: Praziquantel	75 mg/kg/day PO in 3 doses × 1–2 days	Fecal examinations for eggs 1 and 3 mo after therapy
	or Albendazole	10 mg/kg × 7 days	
Cryptosporidium spp.	Drugs of choice: Nitazoxanide	500 mg PO BID × 3 days Children 1–3 yr: 100 mg PO BID × 3 days 4–11 yr: 200 mg PO BID × 3 days >12 yr: 500 mg PO BID × 3 days	Take with food
	or Paromomycin	25–35 mg/kg/day in 2 or 4 doses	Monitor clinical response and perform stool examinations during and after experimental therapy (acid-fast stain or fecal immunoassay); may be combined with azithromycin (600 mg/day)

Cutaneous larva migrans (creeping eruption, dog and cat hookworm) (*Ancylostoma braziliense*, *Ancylostoma caninum*)	Drugs of choice:		
	Albendazole	400 mg PO daily × 3 days	Monitor clinical response to therapy
	or		
	Ivermectin	200 μg/kg PO daily × 1–2 days	
Cyclospora cayetanensis	TMP-SMX	TMP 160 mg, SMX 800 mg (1 DS tab) PO BID × 7–10 days Children: TMP 10 mg/kg, SMX 50 mg/kg/day PO BID × 7–10 days	Monitor clinical course and perform stool examination using modified acid-fast stains or autofluorescence
	Alternative: Ciprofloxacin	500 mg PO BID × 7 days	
Cysticercosis (*Taenia solium*)	Albendazole	15 mg/kg/day (max 800 mg) PO in 2 doses × 8–30 days; can be repeated if necessary	Monitor clinical response to therapy; follow up with CT scans; corticosteroids should be given 2–3 days before and during therapy; damage may occur when treating ocular or spinal cysts, even using corticosteroids; antiseizure medication may also be required; take with food
	or		
	Praziquantel	50 mg/kg/day PO × 15 days	
	or		
	Surgery		
Cystoisospora belli	TMP-SMX	160 mg of TMP, 800 mg of SMX (1 DS tab) PO BID × 10 days Children: TMP 10 mg/kg/day, SMX 50 mg/kg /day PO BID × 10 days	Fecal examinations 1–2 wk after therapy; some areas of endemicity within South America; can be seen in immunocompromised patients
Dientamoeba fragilis	Drugs of choice:		
	Paromomycin	25–35 mg/kg/day PO in 3 doses × 7 days	Fecal examinations 2–4 wk after therapy (must include permanent stained smear); take with meal
	or		
	Iodoquinol	650 mg TID × 20 days Children: 30–40 mg/kg/day (max 2 g) in 3 doses × 20 days	Take after meals
	or		
	Metronidazole	500–750 mg PO TID × 10 days Children: 35–50 mg/kg/day PO in 3 doses × 10 days	In one study, single-dose ornidazole (available in Europe) was effective and better tolerated than metronidazole
Diphyllobothrium latum (broad fish tapeworm)	Drug of choice: Praziquantel	5–10 mg/kg once	Fecal examinations for eggs and proglottids 1 and 3 mo after therapy; take with liquids during a meal
	Alternative: Niclosamide	2 g once Children: 50 mg/kg once	Chew thoroughly or crush, swallow with water

(continued)

TABLE 36.1 Drugs and dosages for treating parasitic infections[a] *(continued)*

Organism or infection	Drug	Dosage[b]	Follow-up[b] and comments
Dipylidium caninum (dog and cat tapeworm)	Drug of choice: Praziquantel	5–10 mg/kg once	Fecal examinations for eggs and proglottids 1 and 3 mo after therapy
	Alternative: Niclosamide	2 g once Children: 50 mg/kg once	
Dracunculus medinensis (guinea worm)	Metronidazole	250 mg TID × 10 days Children: 25 mg/kg/day PO (max 750 mg/day) in 3 doses × 10 days	Monitor clinical course; slow extraction of worm; drugs not curative, but decrease inflammation; wound care and pain management may be sufficient; treat entire household
Echinococcus granulosus (hydatid cyst)	Drugs of choice:		
	Albendazole	15 mg/kg/day (max 800 mg) PO in 2 doses × 1–6 mo	Monitor clinical response to therapy; follow up with CT, ultrasonography, and radionucleotide scans; take with food
	or		
	Surgery		Praziquantel can be used preoperatively or in case of spillage of cyst contents during surgery
Echinococcus multilocularis (alveolar hydatid cyst)	Surgery	If surgery is unsuccessful or contraindicated, albendazole may be used	Monitor clinical response to therapy; follow up with CT, ultrasonography, and radionucleotide scans
	or		
	Albendazole	15 mg/kg/day (max 800 mg) PO in 2 doses ≥2 yrs	Long-term therapy can stabilize but rarely cure infection
Entamoeba histolytica	Drugs of choice:		
	Iodoquinol; taken after meals	650 mg/kg PO TID × 20 days Children: 30–40 mg/kg/day in 3 doses × 20 days (max 2 g)	Fecal examinations 2 wk to 1 mo after therapy (must include permanent stained smear); EIAs for confirmation of true *E. histolytica* are available; trophozoites containing ingested RBCs can be identified as *E. histolytica*
	or		
	Paromomycin; with meal	25–35 mg/kg/day PO in 3 doses × 7 days	
	or		
	Diloxanide furoate (alternative)	500 mg PO TID × 10 days Children: 20 mg/kg/day in 3 doses × 10 days	Not available commercially
Mild to moderate intestinal disease	Metronidazole	500–750 mg PO TID × 7–10 days Children: 35–50 mg/kg/day PO in 3 doses × 7–10 days	Fecal examinations 2 wk to 1 mo after therapy (must include permanent stained smear); EIAs for confirmation of true *E. histolytica* are available; follow up with course of iodoquinol or paromomycin used to treat asymptomatic amebiasis
	or		
	Tinidazole	2 g/day PO × 3 days Children: ≥3 yrs, 50 mg/kg (max 2 g) PO in 1 dose ≥3 days	Tablets can be crushed and mixed with cherry syrup

	Either followed by:		
	Iodoquinol	650 mg PO TID × 20 days Children: 30–40 mg/kg/day (max 2 g) PO in 3 doses × 20 days	
	or		
	Paromomycin	25–35 mg/kg/day PO in 3 doses × 7 days	
Invasive amebiasis	Metronidazole	750 mg PO (or i.v.) TID × 7–10 days Children: 35–50 mg/kg/day PO (or i.v.) in 3 doses × 7–10 days	Monitor clinical response to therapy; follow up with CT, ultrasonography, and radionucleotide scans
	or		
	Tinidazole	2 g once daily PO × 5 days Children: ≥3 yrs, 50 mg/kg/day (max 2 g) PO every day × 5 days	Tablets can be crushed and mixed with cherry syrup
	Either followed by:		
	Iodoquinol	650 mg PO TID × 20 days Children: 30–40 mg/kg/day (max 2 g) PO in 3 doses × 20 days	
	or		
	Paromomycin	25–35 mg/kg/day PO in 3 doses × 7 days	
Entamoeba polecki	Metronidazole	750 mg TID × 10 days Children: 35–50 mg/kg/day in 3 doses × 10 days	Fecal examinations 2 wk to 1 mo after therapy (must include permanent stained smear)
Enterobius vermicularis (pinworm)	Drugs of choice:		Monitor clinical response; follow up with Scotch tape check of perianal area if symptoms persist (may take 4–6 consecutive negative tapes to rule out infection)
	Albendazole	400 mg PO once; repeat after 2 wk	
	or		
	Mebendazole	100 mg once, repeat after 2 wk	
	or		
	Pyrantel pamoate	11 mg/kg base PO once (max 1 g); repeat in 2 wks	
Fasciola hepatica (sheep liver fluke)	Drug of choice: Triclabendazole	10 mg/kg PO once or twice	Fecal examinations for eggs 1 mo after therapy; problems with availability of triclabendazole
	Alternatives:		
	Bithionol	30–50 mg/kg PO on alternate days × 10–15 doses	
	or		
	Nitazoxanide	500 mg PO BID × 7 days Children: 1–3 yrs: 100 mg PO bid × 7 days 4–11 yrs: 200 mg PO bid × 7 days >12 yrs: 500 mg PO bid × 7 days	
Fasciolopsis buski (giant intestinal fluke)	Drug of choice: Praziquantel	75 mg/kg/day PO in 3 doses × 1 day	Fecal examinations for eggs 1 mo after therapy

(continued)

TABLE 36.1 Drugs and dosages for treating parasitic infections[a] *(continued)*

Organism or infection	Drug	Dosage[b]	Follow-up[b] and comments
Giardia lamblia (*G. duodenalis*, *G. intestinalis*)	Drugs of choice:		
	Tinidazole (availability an issue)	2 g PO once Children: ≥3 yrs: 50 mg/kg PO once	Fecal examinations 2 wk to 1 mo posttherapy (must include permanent stained smear or immunoassay); Entero-Test if stools are negative and patient is symptomatic; immunoassays for stool antigen available
	or		
	Metronidazole	250 mg PO TID × 5–7 days Children: 15 mg/kg/day PO in 3 doses × 5–7 days	Fecal examinations 2 wk to 1 mo posttherapy (must include permanent stained smear or immunoassay); Entero-Test if stools are negative and patient is symptomatic; immunoassays for stool antigen available
	or		
	Nitazoxanide	500 mg PO BID × 3 days Children: 1–3 yr: 100 mg PO BID × 3 days 4–11 yr: 200 mg PO BID × 3 days >12 yrs: 500 mg PO BID × 3 days	
	Alternatives:		
	Paromomycin	25–35 mg/kg/day PO in 3 doses × 5–10 days	
	or		
	Furazolidone	100 mg PO QID × 7–10 days Children: 6 mg/kg/day PO in 4 doses × 7–10 days	
	or		
	Quinacrine	100 mg PO TID × 5 days Children: 6 mg/kg/day PO in 3 doses × 5 days (300 mg/day)	Not available commercially
Gnathostoma spinigerum	Surgical removal		Check for additional migratory swellings. Treat all patients with medication whether surgery is attempted or not.
	plus		
	Albendazole	400 mg PO BID × 21 days	
	or		
	Ivermectin	200 µg/kg/day PO × 2 days	
Gongylonema spp.	Surgical removal		Check buccal cavity and esophagus
	plus		
	Albendazole	400 mg PO BID × 3 days	
Heterophyes heterophyes (intestinal fluke)	Praziquantel	75 mg/kg/day PO in 3 doses × 3 days	Fecal examinations for eggs 1 mo after therapy

Hymenolepis nana (dwarf tapeworm)	Drug of choice: Praziquantel	25 mg/kg PO once	Fecal examinations for eggs and proglottids 2 wk and 3 mo after therapy
	Alternative: Niclosamide	2 g PO daily × 7 days Children: 11–34 kg: 1 g PO on day 1, then 500 mg/day PO for 6 days >34 kg: 1.5 g PO on day 1, then 1 g/day PO × 6 days	Must be thoroughly chewed or crushed and swallowed with water
Leishmania spp.	Drugs of choice:		
Cutaneous Mucocutaneous Visceral	Stibogluconate sodium for cutaneous, mucocutaneous; 2nd choice for visceral	20 mg of antimony/kg/day i.v. or i.m. × 20 days	For *L. donovani*, monitor clinical response to therapy; for other *Leishmania* spp., perform smear and culture of lesions 1–2 wk after therapy
	or		
	Meglumine antimonite: 2nd choice for cutaneous and mucocutaneous; 3rd choice for visceral	20 mg of antimony/kg/day i.v. or i.m. × 20 days	
	or		
	Amphotericin B: mucocutaneous	0.5–1.0 mg/kg/day by slow infusion daily or every 2 days for up to 4–8 wk	
	or		
	Liposomal amphotericin B: drug of choice for visceral	18–21 mg/kg over 5 days 3 mg/kg/day i.v. on days 1–5, 14, and 21 (FDA approved) Children: 2 doses of 10 mg/kg each	Immunocompromised: 4 mg/kg on days 1–5, 10, 17, 24, 31, and 38. The total dosage is more important than the number of infusions or duration of therapy.
	or		
	Miltefosine: alternate drug for all three types	2.5 mg/kg/day PO (max 150 mg/day) × 28 days	
	Alternatives :		
	Pentamidine (cutaneous)	2–3 mg/kg daily or every 2 days i.v. or i.m. for 4–7 doses	
	or		
	Paromomycin (cutaneous)	Topically twice daily × 10–20 days	
Lice infestation (*Pediculus humanus*, *Pediculus capitis*, *Phthirus pubis*)	Pyrethrins with piperonyl butoxide	Topically, 2 × at least 7 days apart	Eyelashes, use petrolatum ointment 2–4 × /day × 8–10 days; pubic lice, use 1% permethrin, pyrethrins with piperonyl butoxide, or ivermectin
	or		
	0.5% Ivermectin lotion	Topically once	
	or		
	0.9% Spinosad susp	Topically, 2 × at least 7 days apart	
	or		
	1% Permethrin	Topically, 2 × at least 7 days apart	
	or		

(continued)

TABLE 36.1 Drugs and dosages for treating parasitic infections[a] *(continued)*

Organism or infection	Drug	Dosage[b]	Follow-up[b] and comments
	5% Benzyl alcohol lotion	Topically, 2 × at least 7 days apart	
	or		
	0.5% Malathion	Topically 2 × at least 7 days apart	
	Alternative: Ivermectin	200 or 400 µg/kg PO	Safety in young children and pregnant women not established
Loa loa (African eye worm)	Drug of choice: Diethylcarbamazine (available from CDC) In heavy infections with *Loa loa*, rapid killing of microfilariae can provoke encephalopathy	9 mg/kg /day in 3 doses × 21 days 300 mg once/wk recommended for prevention	Blood smears, Knott concentration, and membrane filtration of blood for microfilariae 2–4 wk after therapy; for patients with no microfilariae in the blood, full doses can be given from day 1; in heavy infections albendazole preferred (slower onset of action and lower risk of encephalopathy), but repeated doses may be required
Mansonella ozzardi	Ivermectin	200 µg/kg PO once	As above; diethylcarbamazine ineffective
Mansonella perstans	Doxycycline	100 or 200 mg/day PO × 6–8 wks	Diethylcarbamazine, mebendazole, ivermectin ineffective against *M. perstans*
Mansonella streptocerca	Diethylcarbamazine (available from CDC)	6 mg/kg/day PO in 3 doses × 12 days	See *Onchocerca volvulus*
	or		
	Ivermectin	150 µg/kg PO once	
Metagonimus yokogawai (intestinal fluke)	Praziquantel	75 mg/kg/day in 3 doses × 1 day	Fecal examinations for eggs 2–4 wk after therapy
Metorchis conjunctus (North American liver fluke)	Praziquantel	75 mg/kg/day PO in 3 doses × 1 day	Fecal examinations for eggs 2–4 wk after therapy
Microsporidia	In some genera and species, treatment not totally effective; see also nitazoxanide under *Giardia lamblia*		
Disseminated			
Encephalitozoon hellem	Albendazole	400 mg BID Children: 15 mg/kg/day in 2 doses (max 400 mg/dose)	Monitor clinical response; dose for children the same for all disseminated infections
Encephalitozoon cuniculi	Albendazole	400 mg BID	Monitor clinical response
Encephalitozoon (Septata) intestinalis	Albendazole	400 mg BID	Monitor clinical response
Pleistophora sp.	Albendazole	400 mg BID	Monitor clinical response; may add itraconazole 400 mg PO once/day
Trachipleistophora spp.	Albendazole	400 mg BID	Monitor clinical response; may add itraconazole 400 mg PO once/day
Anncaliia (Brachiola) vesicularum	Albendazole	400 mg BID	Monitor clinical response; may add itraconazole 400 mg PO once/day

Intestinal			
Enterocytozoon bieneusi	Fumagillin	20 mg PO TID × 14 days	Monitor clinical response; fecal exam for spores 2–4 wk after therapy
Encephalitozoon (*Septata*) *intestinalis*	Albendazole[c]	400 mg BID × 21 days Children: 15 mg/kg/day in 2 doses (max 400 mg/dose)	Monitor clinical response; fecal exam for spores 2–4 wk after therapy
Ocular			
Encephalitozoon hellem	Albendazole plus fumagillin	400 mg BID, eye drops	Monitor clinical response
Encephalitozoon cuniculi	Albendazole plus fumagillin	400 mg BID, eye drops	Monitor clinical response
Vittaforma corneae	Albendazole plus fumagillin	400 mg BID, eye drops	Monitor clinical response
Moniliformis moniliformis	Pyrantel pamoate	11 mg/kg once, repeat twice, 2 wk apart	Fecal exam for eggs 1 mo after therapy
Naegleria fowleri (primary amebic meningoencephalitis)	Amphotericin B (conventional formulation)	0.25 mg/kg/day i.v. over 4–6 h; if tolerated, 0.5 mg/kg i.v. the following day, increasing to 1.5 mg/kg i.v. once/day as tolerated (max 1.5 mg/kg/day)	Monitor clinical response and organisms in CSF; direct wet mounts of CSF and cultures
	Rifampin	10 mg/kg i.v. once/day (max 600 mg/day)	
	Fluconazole	12 mg/kg i.v. once/day	
	Azithromycin	500 mg i.v. once/day Children: 20 mg/kg i.v. once/day (max 500 mg/day)	
Nanophyetus salmincola	Praziquantel	60 mg/kg/day PO in 3 doses × 1 day	Fecal exam for eggs 1 mo after therapy
Oesophagostomum bifurcum	Albendazole	400 mg PO once	Monitor clinical response; pyrantel pamoate may also be effective
	or		
	Pyrantel pamoate	11 mg/kg base (max 1 g) PO once/day × 3 days	
Onchocerca volvulus (river blindness)	Ivermectin	150 µg/kg PO once, repeat every 6–12 mo until asymptomatic	Skin snips for microfilariae 3–6 mo after therapy or sooner if symptoms recur
Opisthorchis viverrini (Southeast Asian liver fluke)	Praziquantel	75 mg/kg/day PO in 3 doses × 2 days	Fecal exam for eggs 1 mo after therapy
	or		
	Albendazole	10 mg/kg/day PO × 7 days	
Paragonimus westermani (lung fluke), *Paragonimus* spp.	Drug of choice: Praziquantel	75 mg/kg/day PO in 3 doses × 2 days	Sputum examination for eggs 2–4 wk after therapy; fecal examinations for eggs 1–2 mo after therapy
	Alternative:		
	Triclabendazole	10 mg/kg PO once or twice	
	or		
	Bithionol	30–50 mg/kg on alternate days × 10–15 doses	

(continued)

TABLE 36.1 Drugs and dosages for treating parasitic infections[a] *(continued)*

Organism or infection	Drug	Dosage[b]	Follow-up[b] and comments
Plasmodium spp. (*P. falciparum*, *P. knowlesi*, *P. malariae*, *P. ovale*, *P. vivax*)			
Oral chemoprophylaxis (prevention) Areas of chloroquine susceptibility	Drug of choice: Chloroquine phosphate	500 mg (300 mg base) once/wk, beginning 1–2 wks before travel, continue weekly for duration of stay and 4 wks after leaving malarious zone Children: 5 mg/kg base once/wk, up to adult dose of 300 mg base; same regimen as adults	No drug guarantees protection against malaria. Travelers should seek medical help if fever develops after returning. Remember to include insect repellents, insecticide-impregnated bed nets and proper clothing, depending on the geographic areas visited.
Areas of chloroquine resistance	Drug of choice: Atovaquone/proguanil	1 adult tab/day, beginning 1–2 days before travel, continue for duration of stay and for 1 wk after leaving malarious area Children: same regimen as adults <5 kg: not indicated 5–8 kg: ½ peds tab/day 9–10 kg: ¾ peds tab/day 11–20 kg: 1 peds tab/day 21–30 kg: 2 peds tabs/day 31–40 kg: 3 peds tabs/day >40 kg: 1 adult tab/day	
	or		
	Doxycycline	100 mg PO daily Children: 2 mg/kg/day PO, up to 100 mg/day	Same regimen as Atovaquone/proguanil
	or		
	Mefloquine	250 mg PO once/wk Children: ≤9 kg: 5 mg/kg salt once/wk 9–19 kg: ¼ tab once/wk 19–30 kg: ½ tab once/wk 31–45 kg: ¾ tab once/wk >45 kg: 1 tab once/wk	
	Alternative: Primaquine phosphate	30 mg base PO daily Children: 0.5 mg/kg base PO daily	
Oral treatment (uncomplicated or mild infection) *P. falciparum* in areas of chloroquine resistance, *P. falciparum* ID or unidentified species	Drug of choice: Atovaquone/proguanil	4 adult tabs PO once/day or 2 adult tabs PO BID × 3 days Children: <5 kg: not indicated 5–8 kg: 2 peds tabs PO once/day × 3 days 9–10 kg: 3 peds tabs PO once/day × 3 days 11–20 kg: 1 peds tab/day PO × 3 days 21–30 kg: 2 peds tabs PO once/day × 3 days 31–40 kg: 3 peds tabs/day × 3 days >40 kg: 1 adult tab/day × 3 days	250 mg/100 mg (1 tablet) daily, beginning 1–2 days before travel, continuing during stay and for 1 wk after leaving area

	or	
	Artemether/lumefantrine	6 doses over 3 days (4 tabs/dose at 0, 8, 24, 36, 48, and 60 h) Children: 6 doses over 3 days at same intervals as adults 5–15 kg: 1 tab/dose >15–25 kg: 2 tabs/dose >25–35 kg: 3 tabs/dose >35 kg: 4 tabs/dose
	or	
	Quinine sulfate	650 mg PO q8h × 3 or 7 days Children: 30 mg/kg/day PO in 3 doses × 3 or 7 days
	plus	
	Doxycycline	100 mg PO BID × 7 days Children: 4 mg/kg/day PO in 2 doses × 7 days
	or plus	
	Tetracycline	250 mg PO QID × 7 days Children: 25 mg/kg/day PO in 4 doses × 7 days
	or plus	
	Clindamycin	20 mg/kg/day PO in 3 doses × 7 days
	Alternative: Mefloquine	750 mg PO followed 12 h later by 500 mg Children: 15 mg/kg PO followed 12 h later by 10 mg/kg
P. vivax in areas of chloroquine resistance, *P. vivax* ID	Drug of choice: Quinine sulfate	650 mg PO q8h × 3 or 7 days Children: 30 mg/kg/day PO in 3 doses × 3 or 7 days
	plus	
	Doxycycline	100 mg PO BID × 7 days Children: 4 mg/kg/day PO in 2 doses × 7 days
	Plus	
	Primaquine phosphate	30 mg base/day PO × 14 days Children: 0.5 mg/kg/day PO × 14 days
	Alternatives:	
	Atovaquone/proguanil	4 adult tabs PO once/day or 2 adult tabs BID, × 3 days Children: <5 kg: not indicated 5–8 kg: 2 peds tabs PO once/day × 3 days 11–20 kg: 1 adult tab PO once/day × 3 days 21–30 kg: 2 adult tabs PO once/day × 3 days 31–40 kg: 3 adult tabs PO once/day × 3 days >40 kg: 4 adult tabs PO once/day × 3 days

(continued)

TABLE 36.1 Drugs and dosages for treating parasitic infections[a] *(continued)*

Organism or infection	Drug	Dosage[b]	Follow-up[b] and comments
	Mefloquine	750 mg PO followed 12 h later by 500 mg Children: 15 mg/kg PO followed 12 h later by 10 mg/kg	
	either plus		
	Primaquine phosphate	30 mg base/day PO × 14 days Children: 0.5 mg/kg/day PO × 14 days	
All *Plasmodium* spp. in areas with no chloroquine resistance	Drug of choice: Chloroquine phosphate	1 g (600 mg base) PO, then 500 mg (300 mg base) 6 h later, then 500 mg (300 mg base) at 24 and 48 h Children: 10 mg base/kg (max 600 mg base) PO, then 5 mg base/kg 6 h later, then 5 mg base/kg at 24 and 48 h	
Parenteral treatment (severe infection) All *Plasmodium* spp. (chloroquine-sensitive and resistant)	Quinidine gluconate	10 mg/kg IV loading dose (max 600 mg) in normal saline over 1–2 h, followed by continuous infusion of 0.02 mg/kg/min until PO therapy can be started	Uncomplicated or mild malaria may be treated with oral drugs. However, severe malaria (impaired consciousness, >5% parasitemia, shock) requires parenteral drugs.
	or		
	Quinine dihydrochloride	20 mg/kg IV loading dose in 5% dextrose over 4 h, followed by 10 mg/kg over 2–4 h every 8 h (max 1,800 mg/day) until PO therapy can be started	
	or		
	Artesunate plus a second oral drug	2.4 mg/kg/dose IV × 3 days at 0, 12, 24, 48, and 72 h	
Oral treatment (self-presumptive treatment)	Atovaquone/proguanil	4 adult tabs daily once/day or 2 adult tabs BID × 3 days Children: <5 kg: not indicated 5–8 kg: 2 peds tabs once/day × 3 days 9–10 kg: 3 peds tabs once/day × 3 days 11–20 kg: 1 adult tab once/day × 3 days 21–30 kg: 2 adult tabs once/day × 3 days 31–40 kg: 3 adult tabs once/day × 3 days >40 kg: 4 adult tabs once/day × 3 days	A traveler can be given a course of atovaquone/proguanil, mefloquine, or quinine plus doxycycline for presumptive self-treatment of febrile illness. The drug used for self-treatment should be different from that used for prophylaxis. This approach should be used in very rare circumstances when the person cannot promptly receive medical care.
	or		
	Artemether/lumefantrine	6 doses over 3 days (4 tabs/dose at 0, 8, 24, 36, 48, and 60 h)	
	or		
	Quinine sulfate	650 mg PO q8h × 3 or 7 days Children: 30 mg/kg/day in 3 doses × 3 or 7 days	
	plus		
	Doxycycline	100 mg PO BID × 7 days Children: 4 mg/kg/day in 2 doses × 7 days	

Sappinia diploidea (amebic meningoencephalitis)	Azithromycin plus	250 mg/day PO × 1 wk	Combined therapy with surgical resection of CNS lesion
	Pentamidine (i.v.) plus	300 mg/day, 6 wk	
	Itraconazole plus	200 mg BID, 25 wk	
	Flucytosine	2.75 g QID, 25 wk	
	Alternatives:		
	Ivermectin	200 µg/kg PO once	
	or		
	10% Crotamiton	Topically once/day × 2	
Sarcoptes scabiei (itch mite)	Drug of choice: 5% Permethrin	Topically; massage from head to soles of feet; wash off after 8–14 h	Monitor clinical course; may need mild steroid cream in sensitive individuals; may require retreatment in 10–14 days; ivermectin plus scabicides recommended for crusted scabies in immunocompromised patients
Schistosoma haematobium	Praziquantel	40 mg/kg/day in 2 doses × 1 day	Urine examinations for eggs 1 mo after therapy; bladder or rectal biopsy; treatment failure reported
Schistosoma intercalatum	Praziquantel	40 mg/kg/day in 2 doses × 1 day	Fecal examinations for eggs 1 mo after therapy; rectal biopsy
Schistosoma japonicum	Praziquantel	60 mg/kg/day in 3 doses × 1 day	Fecal examinations for eggs 1 mo after therapy; rectal biopsy
Schistosoma mansoni	Drug of choice: Praziquantel	40 mg/kg/day in 2 doses × 1 day	Fecal examinations for eggs 1 mo after therapy; rectal biopsy
	Alternative: Oxamniquine	15 mg/kg once Children: 20 mg/kg/day in 2 doses × 1 day	Contraindicated in pregnancy; East Africa, increase dose to 30 mg/kg; South Africa, increase dose to 30 mg/kg × 2 days
Schistosoma mekongi	Praziquantel	60 mg/kg/day in 3 doses × 1 day	Fecal examinations for eggs 1 mo after therapy; rectal biopsy
Strongyloides stercoralis	Drug of choice: Ivermectin	200 µg/kg/day PO × 2 days	Fecal examinations and/or agar plate culture 1 mo after therapy
	Alternative: Albendazole	400 mg BID × 7 days	
Taenia saginata (beef tapeworm)	Drug of choice: Praziquantel	5–10 mg/kg PO once	Fecal examinations for eggs or proglottids 1 mo after therapy
Taenia solium (pork tapeworm) Adult tapeworms	Alternative: Niclosamide	2 g PO once Children: 50 mg/kg PO once	Availability problems
Toxocara canis, T. cati (visceral larva migrans)	Albendazole	400 mg BID PO × 5 days	Monitor clinical course; some consultants recommend treating for 20 days; severe symptom or eye involvement, treat for 2–4 wks and can add corticosteroids
	or		
	Mebendazole	100–200 mg PO BID × 5 days	

(continued)

TABLE 36.1 Drugs and dosages for treating parasitic infections[a] *(continued)*

Organism or infection	Drug	Dosage[b]	Follow-up[b] and comments
Toxoplasma gondii	Drugs of choice:		
	Pyrimethamine	200 mg PO × 1 day, then 50–75 mg/day PO × 3–6 wks	Monitor clinical course and serology; use only after first trimester
		Children: 2 mg/kg/day PO × 2 days, then 1 mg/kg/day (max 25 mg/day) × 3–6 wks	
	plus		
	Sulfadiazine	1–1.5 g PO QID × 3–6 wks	
		Children: 100–200 mg/kg divided every 6 h PO × 3–6 wks	
	or plus		
	Clindamycin	1.8–2.4 g/day i.v. or PO in 3 or 4 doses	
		Children: 5–7.5 mg/kg/day i.v. or PO in 3 or 4 doses (max 600 mg/dose)	
	or plus		
	Atovaquone	1,500 mg PO BID	
	Alternatives:		
	TMP/SMX	TMP 15–20 mg/kg/day SMX 75–100 mg/kg/day PO or i.v. in 3 or 4 doses	
	or		
	Spiramycin (alternative)	3–4 g/day × 3–4 weeks	Can be used during first-trimester infection
Trichinella spiralis, other Trichinella spp.	Drugs of choice:		
	Mebendazole	200–400 mg TID × 3 days, then 400–500 mg TID × 10 days	Monitor clinical course; perform muscle biopsy in severe cases; steroids for severe symptoms
	plus		
	Corticosteroids	Prednisone: 20–60 mg/day PO daily × 10–15 days	Use for severe symptoms
	Albendazole (alternative)	400 mg PO BID × 8–14 days	
Trichomonas vaginalis	Tinidazole	2 g PO once Children: 50 mg/kg once (max 2 g)	Pelvic examination 1 mo after therapy; sexual partners should be treated simultaneously
	or		
	Metronidazole	2 g PO once Children: 15 mg/kg/day PO in 3 doses × 7 days	Take with food to minimize adverse side effects; can be used with metronidazole-resistant strains
Trichostrongylus spp.	Drug of choice: Pyrantel pamoate	11 mg/kg base PO once (max 1 g)	Fecal examinations 2–4 wk after therapy
	Alternatives:		
	Mebendazole	100 mg PO BID × 3 days	
	or		
	Albendazole	400 mg PO once	
Trichuris trichiura (whipworm)	Drug of choice: Albendazole	400 mg PO × 3 days	Fecal examinations 2–4 wk after therapy
	Alternatives:		
	Mebendazole	100 mg PO BID × 3 days	
	or		
	Ivermectin	200 µg/kg/day PO × 3 days	

Tropical pulmonary eosinophilia	Diethylcarbamazine (available from CDC)	6 mg/kg/day in 3 doses × 12–21 days	Monitor clinical course; if relapse occurs, re-treat
Trypanosoma brucei gambiense (West African sleeping sickness), early stages (hemolymphatic)	Drug of choice: Pentamidine Alternative: Suramin	4 mg/kg/day i.m. or i.v. × 7 days 100 mg (test dose) i.v., then 1 g i.v. on days 1, 3, 5, 14, and 21 Children: 2 mg/kg (test dose) i.v., then 20 mg/kg i.v. on days 1, 3, 5, 14, and 21	Thick and thin blood smears 1–2 mo after therapy
Trypanosoma brucei rhodesiense (East African sleeping sickness), early stages (hemolymphatic)	Suramin	100 mg (test dose) i.v., then 1 g i.v. on days 1, 3, 5, 14, and 21 Children: 2 mg/kg (test dose) i.v., then 20 mg/kg i.v. on days 1, 3, 5, 14, and 21	
T. brucei gambiense and *T. brucei rhodesiense,* late stage with CNS disease	Melarsoprol (first choice for Rhodesian form)	2.2 mg/kg/day i.v. × 10 days Children: 18–25 mg/kg total over 1 mo; initial dose of 0.36 mg/kg i.v., increasing gradually to max of 3.6 mg/kg at intervals of 1–5 days for total of 9–10 doses	CSF analysis during and after therapy
	or		
	Eflornithine (first choice for Gambian form)	400 mg/kg/day i.v. in 4 doses × 14 days	Highly effective for *T. brucei gambiense* but variable for *T. brucei rhodesiense*
	or		
	Eflornithine plus nifurtimox	15 mg/kg/day PO in 3 doses × 10 days	
Trypanosoma cruzi (American trypanosomiasis, Chagas' disease)	Benznidazole	5–7 mg/kg/day PO in 2 divided doses × 60 days Children ≤12 yr: 10 mg/kg/day PO in 2 doses × 60 days >12 yrs: 5–7 mg/kg/day PO in 2 doses × 60 days	Thick and thin blood smears or xenodiagnosis 1–2 mo after therapy; monitor serology and EKG
	or		
	Nifurtimox	8–10 mg/kg/day PO in 3–4 doses × 90 days Children: 1–10 yr: 15–20 mg/kg/day PO in 4 doses × 90 days 11–16 yr: 12.5–15 mg/kg/day PO in 4 doses × 90 days	
Wuchereria bancrofti	Diethylcarbamazine (available from CDC)	6 mg/kg/day PO in 3 doses × 1 or 12 days	Thick blood smears, Knott concentration, and membrane filtration of blood after 2–4 wks

---

[a] It is **very important** to thoroughly review drug information prior to use and to review published commentary concerning availability, contraindications, and monitoring requirements. Specific information can also be obtained online by checking *The Medical Letter*, vol 11, 2013 (The Medical Letter, New Rochelle, NY, http://www.medletter.com/freedocs/parasitic.pdf [accessed June 23, 2014]).

[b] BID, twice a day; TID, three times a day; QID, four times a day. CDC, Centers for Disease Control and Prevention; CNS, central nervous system; CSF, cerebrospinal fluid; CT, computed tomography; DS tab, double-strength tablet; EIA, enzyme immunoassay; EKG, electrocardiogram; i.m., intramuscular; i.v., intravenous; max, maximum; peds, pediatric; PHMB, polyhexamethylene biguanide; PO, orally; PC, with meals; SMX, sulfamethoxazole; TMP, trimethoprim.

TABLE 36.2 Antiparasitic drugs[a]

Drug	Manufacturer	Trade name and comments
Albendazole	Amedra	Albenza
Aminosidine		See Paromomycin
Amphotericin B	X-Gen	Fungizone, generics
Amphotericin B, liposomal	Gilead	AmBisome
Artemether[b]	Arenco, Belgium	Artenam; not available in the United States
Artemether/lumefantrine	Novartis	Coartem, Riamet
Artesunate[e]	Guilin No. 1 Factory, People's Republic of China	Not available in the United States
Atovaquone	GlaxoSmithKline	Mepron
Atovaquone-proguanil	GlaxoSmithKline	Malarone
Azithromycin	Pfizer	Zithromax
Bacitracin	Many manufacturers	
Benznidazole[c]	Roche, Brazil	Rochagan; not available in the United States
Bithionol[b]		Bitin; available through CDC Drug Service
Chloroquine HCl, chloroquine phosphate	Sanofi, others	Aralen, generics
Clarithromycin	Abbvie	Biaxin, generics
Clindamycin	Pfizer, others	Cleocin, generics
Crotamiton	Ranbaxy	Eurax
Dapsone	Jacobus	Generics
Diethylcarbamazine citrate (DEC)[c]		Hetrazan; available through CDC Drug Service
Dihydroartemisin/piperaquine	Sanofi	Euratesim
Diloxanide furoate[b]	Boots, United Kingdom	Furamide, Entamide; not available in the United States
Doxycycline	Pfizer, others	Vibramycin; also available generically
Eflornithine (difluoromethylornithine, DFMO)[c]	Sanofi	Ornidyl; available through CDC Drug Service
Fluconazole	Pfizer	Diflucan, generics
Flucytosine	Valeant	Ancobon
Fumagillin[b]	Leiter's Park Avenue Pharmacy, San Jose, CA (800-292-6773) (www.leiterrx.com); Sanofi, France	Flisint, not available in the United States
Furazolidone[b]		Furoxone; not available in the United States
Iodoquinol	Glenwood, others	Yodoxin; generics
Itraconazole	Janssen	Sporanox
Ivermectin	Merck, Sanofi	Stromectol, Sklice
Ketoconazole	Janssen, others	Nizoral; generics
Lumefantrine/Artemether	Novartis	Coartem, Riamet
Levamisole	Janssen	Ergamisol
Malathion	Taro	Ovide
Mebendazole		Generics
Mefloquine		Generics
Meglumine antimoniate[b]	Sanofi, France	Glucantime; not available in the United States
Melarsoprol[c]		Mel-B; available through CDC Drug Service
Metronidazole	Pfizer/Searle	Flagyl; generics
Metronidazole IV	Baxter	
Miconazole[b]		Monistat
Miltefosine[c,d]	Paladin, Canada	Impavido, Miltex; not available in the United States
Niclosamide[b]		Yomesan; not available in the United States
Nifurtimox[c]	Bayer HealthCare	Lampit; available through CDC Drug Service

(continued)

TABLE 36.2 *(continued)*

Drug	Manufacturer	Trade name and comments
Nitazoxanide	Romark	Alinia
Ornidazole[b]		Tiberal; not available in the United States
Oxamniquine[b]	Pfizer	Vansil; not available in the United States
Paromomycin	Sun Pharma	Oral: generics Topical: Leshcutan[b]
Pentamidine isethionate	APP Pharmaceuticals	Pentam 300, NebuPent
Permethrin	Insight, Bayer	Nix
	Prestium Pharma	Elimite, generics
Piperaquine/dihydroartemisin	Sigma Tau, Italy	Euratesim
Praziquantel	Bayer	Biltricide
Primaquine phosphate USP	Sanofi-Aventis	
Proguanil[b]		Paludrine; not available in the United States
Proguanil-atovaquone	GlaxoSmithKline	Malarone
Propamidine isethionate[b]	Aventis	Brolene; not available in the United States
Pyrantel pamoate	Quartz Specialty Pharmaceuticals, Reese	Pin-X, Reese's Pinworm Medicine
Pyrethrins and piperonyl butoxide	Bayer	Rid; generics
Pyrimethamine USP[b]	Amedra	Daraprim
Quinidine gluconate	Generics	
Quinine dihydrochloride		
Quinine sulfate	AR Scientific	Qualaquin
Rifampin	Sanofi	Rifadin; generics
Sodium stibogluconate[c]	GlaxoSmithKline, United Kingdom	Pentostam; available through CDC Drug Service
Spiramycin[e]	Sanofi	Rovamycine
Sulfadiazine	Generics	
Suramin sodium[c]	Bayer, Germany	Germanin; available through CDC Drug Service
Thiabendazole	Merck	Mintezol
Tinidazole	Mission Pharmaceuticals	Tindamax
TMP/Sulfa (TMP/SMX)	Sun Pharma	Bactrim; generics
Triclabendazole[b]	Novartis	Egaten; not available in the United States
Trimetrexate[b]		Neutrexin

[a] Information from reference 1.

[b] Not available in the United States; may be available through a compounding pharmacy such as Expert Compounding Pharmacy, 6744 Balboa Blvd., Lake Balboa, CA 91406 (800-247-9767) or Medical Center Pharmacy, New Haven, CT (203-688-7064). Other compounding pharmacies may be found through the National Association of Compounding Pharmacies (800-687-7850) or the Professional Compounding Centers of America (800-331-2498, www.pccarx.com).

[c] Available from the CDC Drug Service, Centers for Disease Control and Prevention, Atlanta, GA 30333; 404-639-3670 (evenings, weekends, or holidays: 770-488-7100; fax: 404-639-3717).

[d] Available from the CDC for treatment of infections with free-living amebae; available from the manufacturer through an Investigational New Drug (IND) application from the U.S. Food and Drug Administration (FDA) for treatment of other infections.

[e] Available through an IND request from the FDA. IND request paperwork is available through the CDC.

Amphotericin B (Fungizone) (X-Gen)

Preparation

Fungizone is supplied in vials containing 50 mg of amphotericin B, 4 mg of sodium deoxycholate, and 20.2 mg of sodium phosphate as a buffer. It should be stored in the refrigerator and protected from light. It may be reconstituted by the addition of 10 ml of sterile water for injection USP, without a bacteriostatic agent, to make a 5-mg/ml solution. This may be further diluted by adding 1 ml of the 5-mg/ml solution to 50 ml of 5% glucose solution to make a final concentration of 0.1 mg of amphotericin per ml. The pH of the solution should be above 4.2. Amphotericin B solutions have been diluted with cerebrospinal fluid before intrathecal administration.

Administration

Therapy is usually initiated with a test dose of 0.25 mg/kg/day and gradually increased to a maximum dose of 1.5 mg/kg/day. It must be given slowly i.v., usually over a 6-

h period. Alternate-day therapy may be better tolerated. For patients with severe life-threatening infections, therapy may have to be initiated with high doses. It may be given intrathecally in the lumbar or cisternal areas. Low doses should be given if the drug is administered intraventricularly.

Toxicity

Nausea, vomiting, fever, and phlebitis are common. Some degree of renal impairment usually occurs and is dose related. Renal function (blood urea nitrogen or serum creatine) should initially be monitored daily. Other side effects include anaphylaxis, hypokalemia, hypotension, anemia, and cardiac dysrhythmias. The side effects are much milder when amphotericin B is delivered in liposomes (AmBisome). This preparation is more expensive but makes the drug more tolerable, especially in patients with known renal failure. The main side effects of liposomal preparations are hypersensitivity reactions.

Contraindications

It may be necessary to pretreat the patient with antiemetic agents or antipyretic drugs. For patients with known hypersensitivity to the drug, it should be used only in life-threatening situations. Concomitant use of other nephrotoxic drugs should be avoided. Extreme caution should be used when the patient is taking other nephrotoxic drugs such as aminoglycosides, high-dose i.v. acyclovir, ganciclovir, foscarnet, and pentamidine. Corticosteroids and adrenocorticotropic hormone may lead to hypokalemia. The drug may increase the bone marrow toxicity of ganciclovir. Probenecid may increase the levels of amphotericin B.

Artemether (Artenam) (Aarenco, Belgium)

Preparation

Artemether is oil soluble and available in tablet, capsule, or intramuscular-injection forms. Artesunate is water soluble and can be given i.v., intramuscularly, orally, or by suppository. The activity of these artemisinin derivatives decreases after 1 to 2 h. To counter this drawback, artemisinin is given alongside lumefantrine to treat uncomplicated falciparum malaria. Lumefantrine has a half-life of about 3 to 6 days. Such a treatment is called ACT (artemisinin-based combination therapy); other examples are artemether-lumefantrine, artesunate-mefloquine, artesunate-amodiaquine, and artesunate-sulfadoxine/pyrimethamine. The artemisinin-based combinations artemether-lumefantrine and artesunate-mefloquine remain highly effective and elicit equivalent therapeutic responses in the treatment of highly drug-resistant falciparum malaria.

Administration

The drugs are given as 250-mg tablets of artemisinin and artesunate orally; they are also available as capsules containing 100 mg of artemisinin. Drugs that are available include artemether-lumefantrine (Coartem) (Novartis).

Toxicity

The artemisinin derivatives are well tolerated, with no serious toxicity or adverse effects. With artemether/lumefantrine, there may be abdominal pain, anorexia, headache, dizziness, diarrhea, vomiting, nausea, palpitations, arthralgia, myalgia, asthenia, fatigue, pruritus, rash, sleep disorder, and cough. With artemether, there may be occasional neurological toxicity.

Contraindications

These drugs should be used with caution in individuals with hepatic or renal impairment. They should be avoided in pregnancy due to insufficient safety information.

Comment

Artemisia annua is a plant with a strong aroma, containing camphor and essential oils. It is a robust plant that grows in many areas of the world. However, only plants grown under special agricultural and geographic conditions contain artemisinin. The best high-yielding samples have been collected from the steep hills at altitudes over 4,500 feet around Youyang County, City of Chongqing, in Szechuan Province, China.

These drugs act mainly against the asexual erythrocytic stages of malaria. High concentrations of iron are found in red blood cells, which is also where the malaria parasites are found. When the compound enters the red blood cell, it releases free radicals, which are highly destructive to the parasites. An alternative theory suggests that artemisinins inhibit a calcium transporter in the parasite and, by specifically inhibiting this target, kill the parasites. The peroxide group in artemisinins is still crucial to activity, but the target is highly selected rather than a result of “explosion” into activity by free radicals. These drugs are also active against gametocytes by about 90% but are not effective against the intrahepatic stage of *P. vivax* and *P. ovale*.

Atovaquone (Mepron) (GlaxoSmithKline)

Preparation

Atovaquone suspension is a formulation of microfine particles of the drug. The atovaquone particles, reduced in size to facilitate absorption, are significantly smaller than those in the previously marketed tablet formulation. The suspension is for oral administration and is bright yellow with a citrus flavor, containing 150 mg of atovaquone per ml or 750 mg of atovaquone in each teaspoonful (5 ml).

Administration

The drug is given orally with meals; it is used to treat *Babesia* spp. and *Pneumocystis jirovecii* (now classified with the fungi) infections. Administering atovaquone with food enhances its absorption by approximately 2-fold.

Toxicity

Mepron may cause nausea, vomiting, diarrhea, and skin rashes, as well as sweating, flu syndrome, pain, sinusitis, insomnia, depression, and myalgia. Monitor for hepatitis, elevated liver function tests and liver failure.

Contraindications

Mepron should not be given to anyone who has developed or has a history of life-threatening reactions to any of the components of the formulation. If it is necessary to treat patients with severe hepatic or renal impairment, caution is advised and administration should be closely monitored. This drug should be used in pregnancy only if the potential benefits outweigh the potential risks to the fetus. It should not be used during lactation.

Atovaquone-Proguanil (Malarone) (GlaxoSmithKline)

Preparation

Malarone (atovaquone and proguanil hydrochloride) is a fixed-dose combination of the antimalarial agents atovaquone and proguanil hydrochloride. Each tablet contains 250 mg of atovaquone and 100 mg of proguanil hydrochloride, and each pediatric tablet contains 62.5 mg of atovaquone and 25 mg of proguanil hydrochloride.

Administration

The drug is given orally with meals or a milky drink; atovaquone and cycloguanil (an active metabolite of proguanil) are active against the erythrocytic and exoerythrocytic stages of *Plasmodium* spp. Malarone is indicated for the prophylaxis of *P. falciparum* malaria, including in areas where chloroquine resistance has been reported. It is also indicated for the treatment of acute, uncomplicated *P. falciparum* malaria and is effective in regions where the drugs chloroquine, halofantrine, mefloquine, and amodiaquine may have unacceptable failure rates, presumably due to drug resistance.

Toxicity

Malarone may cause abdominal pain, nausea, vomiting, headache, diarrhea, asthenia, anorexia, and dizziness. About 5 to 10% of patients have transient asymptomatic elevations in transaminase and amylase levels.

Contraindications

Malarone should not be given to anyone who has developed or has a history of life-threatening reactions to any of the components of the formulation. Rare cases of anaphylaxis following treatment with atovaquone-proguanil have been reported. Due to the lack of safety data, the drug should be avoided during pregnancy or lactation or in patients with renal or hepatic impairment. Malarone has not been evaluated for the treatment of cerebral malaria or other severe manifestations of complicated malaria, including hyperparasitemia, pulmonary edema, or renal failure.

Comment

The drug interferes with two different pathways involved in the biosynthesis of pyrimidines required for nucleic acid replication. Atovaquone is a selective inhibitor of parasite mitochondrial electron transport, while the metabolite of proguanil hydrochloride, cycloguanil, is a dihydrofolate reductase inhibitor. Malarone is effective against asexual and sexual forms of *P. falciparum* and is used for prophylaxis and treatment. Unfortunately, resistance and drug failures are being reported for *P. falciparum*. Although the drug is also effective for treating *P. vivax* and *P. ovale,* primaquine is required to prevent relapses from the liver.

Benznidazole (Rochagan) (Roche, Brazil)

Preparation

Benznidazole is a 2-nitroimidazole derivative and is provided as 100-mg tablets. It is used to treat acute Chagas' disease but is not available in the United States.

Administration

The drug should be taken with meals, preferably after breakfast and after supper, to decrease the chance of stomach upset.

Toxicity

Side effects are seen in many individuals and include nausea, vomiting, abdominal pain, peripheral neuropathy, severe skin reactions, bone marrow suppression, and psychic disturbances.

Contraindications

Alcohol should be avoided during treatment. The drug has been noted to cause lymphoma in animal models and is mutagenic. Its use is not recommended during the first trimester of pregnancy. Benznidazole should not be used with anticoagulants or in patients who have renal or hepatic impairment. Although this side effect is rare, benznidazole can lower the number of white blood cells, increasing the patient's chance of getting an infection. It can also lower the number of platelets, which are necessary for proper blood clotting.

Comment

Benznidazole inhibits protein and RNA synthesis in *Trypanosoma cruzi;* it causes increased phagocytosis, cytokine release, and production of reactive mitogen intermediates that lead to death of the parasites.

Bithionol (Bitin) (CDC)

Preparation

Bitin is supplied as 500-mg capsules, which must be obtained from CDC. The drug is used to treat several trematode infections.

Administration

The capsules are taken orally with meals to minimize stomach irritation.

Toxicity

Patients may experience anorexia, nausea, vomiting, abdominal discomfort, diarrhea, dizziness, and headaches.

Contraindications

Bitin may cause leukopenia and toxic hepatitis, and photosensitization has occurred.

Comment

Bithionol, an investigational drug, is a phenolic substance structurally related to hexachlorophene. It is used as an alternative drug to praziquantel for treating *Paragonimus* infections. It can be used to treat extrapulmonary infections with *Paragonimus*, but multiple courses may be required for cure. Surgery may be needed to excise skin lesions or, rarely, brain cysts. Bithionol is also used to treat *Fasciola hepatica* infections. Its use is limited to treating either of these infections in patients who are unable to tolerate praziquantel due to previous reactions or in whom a previous course of praziquantel was ineffective.

Chloroquine Phosphate (Aralen) (Sanofi, Others)

Preparation

Aralen is supplied in 250- and 500-mg tablets of the diphosphate salt (500 mg of salt = 300 mg of base) and as a hydrochloride for parenteral injection in 5-ml vials containing 40 mg of base per ml. A liquid preparation (Nivaquine) is available outside the United States and is used as an antimalarial agent.

Administration

Aralen is given orally as per protocol for chemoprophylaxis or treatment of an acute attack. Pills can be ground up and placed in sweetened juice or fruit for administration to young children.

Toxicity

Side effects may be dose related and include gastrointestinal symptoms, skin rash, insomnia, headache, and nervousness. Rare reactions such as toxic psychosis and retinal damage, blood dyscrasias, and photophobia may occur.

Contraindications

Relative contraindications include liver, hematologic, and/or neurologic disease; psoriasis; and porphyria. It may be used in pregnant women when necessary for protection. Use of this drug is contraindicated in the presence of retinal or visual field changes either attributable to 4-aminoquinoline compounds or to any other etiology and in patients with known hypersensitivity to 4-aminoquinoline compounds. Parenteral chloroquine may cause hypotension, shock, and sudden death when given to young children.

Comment

Chloroquine is active against the erythrocytic forms of *Plasmodium vivax*, *P. malariae*, and susceptible strains of *P. falciparum* (but not the gametocytes of *P. falciparum*). It is not effective against exoerythrocytic forms of the parasite. Resistance of *P. falciparum* to chloroquine is widespread, and cases of *P. vivax* resistance have been reported.

Crotamiton (Eurax) (Ranbaxy)

Preparation

Eurax is supplied as a 10% cream or lotion and is used to treat scabies (*Sarcoptes scabiei*).

Administration

The cream or lotion is applied to the whole body surface below the chin after bathing and drying. A second application is advisable after 24 h. Reinfection from contaminated clothing and bed linens should be avoided.

Toxicity

The drug can cause irritation and sensitivity reactions, which may include rash or conjunctivitis.

Contraindications

The drug should not be used in the presence of acute exudative dermatitis and should not be applied near the eyes.

Dapsone (Jacobus)

Preparation

Dapsone is supplied as 25- and 100-mg scored tablets and used to treat *Plasmodium falciparum* (combination therapy) and *Pneumocystis jirovecii* (now classified with the fungi) infections.

Administration

Dapsone should be taken orally, and the dosage should be individually titrated.

Toxicity

Dapsone has been associated with frequent rashes, transient headaches, gastrointestinal irritation, anorexia, and infectious mononucleosis-like syndrome. The drug is carcinogenic in animal models. Complete blood counts should be performed frequently because the drug has been associated with death from agranulocytosis, aplastic anemia, and other blood dyscrasias.

Contraindications

The drug should not be given to patients with hypersensitivity to dapsone. Hemolysis and Heinz body formation may be exaggerated in individuals with a glucose-6-phosphate dehydrogenase (G6PDH) deficiency, or methemoglobin reductase deficiency, or hemoglobin M. This reaction is frequently dose related. Dapsone should be given with caution to these patients or to patients who have been exposed to other agents or conditions such as infection or diabetic ketosis capable of producing hemolysis.

Diethylcarbamazine Citrate USP (Hetrazan) (CDC)

Preparation

Diethylcarbamazine is a piperazine derivative and is supplied in 50-mg tablets. It is used to treat filariasis and is effective against microfilariae; it is available from CDC. Hetrazan is effective against *Wuchereria bancrofti*, *Brugia malayi*, *B. timori*, *Onchocerca volvulus*, *Loa loa*, and *Mansonella streptocerca* but has little effect on *M. perstans* or *M. ozzardi*.

Administration

Tablets are scored to provide the appropriate dose. Medication should be taken after meals, adhering to a strict dosage schedule.

Toxicity

Reactions occur frequently and include headache, weakness, malaise, fever, joint pain, anorexia, nausea, and vomiting. These generally subside as therapy continues. Mild to severe reactions, including fever, rash, lymphadenopathy, conjunctivitis, leukocytosis, and eosinophilia, may occur in response to the parasite's death. Severe reaction may require steroid therapy and antihistamines.

Contraindications

Treatment of patients with heavy microfilaremia due to loiasis may cause allergic encephalitis, nephritis, or myocarditis. Patients with many microfilariae or onchocerciasis in ocular tissues may experience keratitis, chorioretinitis, and optic neuritis. Dose reductions are generally required in patients with renal impairment. The drug should probably be avoided in pregnancy but is not excreted in breast milk.

Comment

Diethylcarbamazine citrate, an investigational drug, is an anthelmintic agent that does not resemble other antiparasitic compounds. It is a synthetic organic compound which is highly specific for several parasites and does not contain any toxic metallic elements. It is used to treat patients with certain filarial infections, including lymphatic filariasis (*W. bancrofti*, *B. malayi*, or *B. timori*), tropical pulmonary eosinophilia, and loiasis (*Loa loa*). Treatment of lymphatic filariasis is problematic. Diethylcarbamazine kills microfilariae but only a variable proportion of adult worms. Another drug, ivermectin, rapidly reduces microfilaremia levels and may inhibit larval development in mosquitoes, but it does not kill adult worms and is not very effective against brugian filariasis.

Diloxanide Furoate (Furamide, Entamide) (Boots, England)

Preparation

Diloxanide furoate is supplied as scored 500-mg tablets and is used to treat amebiasis; it is not available in the United States. The drug is hydrolyzed in the bowel to the active compound, diloxanide, which is >90% absorbed.

Administration

Furamide is given by mouth with repeated treatments as necessary.

Toxicity

The most common adverse effect is flatulence. Other side effects are seen, including vomiting, pruritus, and urticaria.

Contraindications

The use of Furamide is generally not recommended during pregnancy or lactation.

Comment

The drug helps clear the bowel of *Entamoeba histolytica* cysts; however, it is not effective for treating invasive disease in the bowel wall or liver. For this reason, it is often given with a 5-nitroimidazole.

Eflornithine (Difluoromethylornithine, Ornidyl) (Sanofi) (CDC)

Preparation

The drug is available as a 200-mg/ml solution, and is used to treat African trypanosomiasis.

Administration

Ornidyl is given as a continuous i.v. infusion or orally; however, oral administration is usually followed by diarrhea. Eflornithine crosses the blood-brain barrier; thus it is beneficial for central nervous system disease associated with African trypanosomiasis.

Toxicity

Side effects occur in about 40% of patients; they include anemia, leukopenia, thrombocytopenia, diarrhea, abdominal discomfort, hearing loss, vomiting, dizziness, arthralgia, and numbness of the limbs.

Contraindications

Ornidyl should not be given with other i.v. drugs. It may worsen hemolytic disorders. Due to insufficient safety data, the drug should not be used during pregnancy or lactation.

Comment

Eflornithine inhibits ornithine decarboxylase, an enzyme required for the formation of polyamines, thus leading to inhibition of parasite growth. However, it is ineffective as monotherapy for *T. brucei rhodesiense.*

Fumagillin (Fumidil-B)

Preparation

The drug is supplied as a 10-mg/ml suspension in physiologic saline. Ocular lesions due to *Encephalitozoon hellem* and *Encephalitozoon cuniculi* have responded to fumagillin eye drops prepared from Fumidil-B used to control microsporidial infection in honeybees. For lesions due to *Vittaforma corneae*, topical therapy is generally not effective and keratoplasty may be required. It has also been used to treat infections with *Enterocytozoon bieneusi* in the gastrointestinal tract. The drug is available in limited supply from CDC and the World Health Organization.

Administration

Fumagillin should be applied topically once an hour until clinical improvement is demonstrated.

Toxicity

The soluble salt is toxic and should not be ingested; topical application is not toxic to the cornea.

Contraindications

No information is available.

Comment

Relapse may occur on discontinuation of fumagillin therapy.

Furazolidone (Furoxone)

Preparation

Furoxone is supplied as 100-mg tablets or as a flavored suspension of 50 mg/liter and is used to treat giardiasis. This drug is not available in the United States.

Administration

The drug is given orally. Apparently furazolidone is more effective by 50% than metronidazole in inhibiting *in vitro* cyst differentiation of *Giardia lamblia.*

Toxicity

Furoxone can cause polyneuritis, nausea, vomiting, dizziness, drowsiness, and general malaise. Skin rashes and agranulocytosis have occasionally been reported. Furazolidone is chemically similar to nitrofurantoin, which is well known to cause pulmonary hypersensitivity reactions; furazolidone may also induce pulmonary hypersensitivity reactions, and clinicians should be aware of this potentially serious adverse effect.

Contraindications

The drug should not be given to individuals hypersensitive to furazolidone or to infants younger than 1 month. Hemolytic anemia can occur in patients with G6PDH deficiency. Alcohol should be avoided during treatment, because disulfiram-like reactions have been reported. Furazolidone is a monoamine oxidase inhibitor and should not be given concomitantly with other similar drugs.

Iodoquinol/Diiodohydroxyquin (Yodoxin) (Glenwood, Others)

Preparation

Iodoquinol/diiodohydroxyquin is supplied as 210- and 650-mg tablets and is used as an amebicide against *Entamoeba histolytica.* The drug is considered effective against the trophozoite and cyst forms.

Administration

The drug should be given with meals. For young children, a suspension may be made by mixing the pulverized tablet with cherry syrup to give a suspension containing 200 to 400 mg/5 ml. The drug is poorly absorbed.

Toxicity

There may be various forms of skin eruptions, urticaria, and pruritus. There may also be nausea, vomiting, abdominal cramps, diarrhea, and pruritus ani. Fever, chills, headache, vertigo, and enlargement of the thyroid have been reported. Optic neuritis, optic atrophy, and peripheral neuropathy have been reported in association with prolonged high-dosage 8-hydroxyquinoline therapy.

Contraindications

Iodoquinol should not be given to patients with known hypersensitivity to iodine or any 8-hydroxyquinoline compound, with renal or thyroid disease, or with severe liver disease not due to amebiasis. Iodoquinol should be used with caution in patients with thyroid disease. Protein-bound serum iodine levels may be increased during treatment with iodoquinol and may interfere with certain thyroid function tests. These effects may persist for as long as 6 months after discontinuation of therapy; this effect is unrelated to thyroid function. The drug should be withdrawn if hypersensitivity reactions occur. Severe neurologic damage, including optic neuritis, optic atrophy, and peripheral neuropathy, has occurred with prolonged high doses of this drug. The recommended doses and duration of therapy should not be exceeded. There may be persistent elevation of the protein-bound iodine level months after therapy. Because of the limited safety data available, this drug should probably be avoided during pregnancy or lactation.

Comment

The drug is thought to act by inactivating parasitic enzymes and inhibiting organism multiplication. Although it is effective for treating intestinal organisms, it is not effective for treating invasive disease in the bowel wall or liver; it is often combined with a 5-nitroimidazole. It has documented activity against *Balantidium coli*, *Dientamoeba fragilis*, *Giardia lamblia*, and *Blastocystis* spp.

Ivermectin (Stromectol, Sklice) (Merck, Sanofi)

Preparation

The drug is available in 3-mg or 6-mg tablets and is a semisynthetic macrolide used to treat nondisseminated strongyloidiasis and filariasis, particularly onchocerciasis (no activity against adult *Onchocerca volvulus* parasites). It is also now used for the treatment of ectoparasitic infestations such as scabies and lice, although it has no effect on the eggs (nits).

Administration

The drug is given orally with water 1 h before breakfast and is rapidly absorbed after ingestion.

Toxicity

The drug can cause fever, headache, rash, increased pruritus, joint and muscle pain, and tachycardia. A Mazzotti-type reaction has been seen in patients with onchocerciasis. Most adverse effects are a result of the host immune response to destruction of the parasites rather than effects of the drug itself. When used for ectoparasites, monitor for conjunctivitis, ocular hyperemia, eye irritation, dandruff, dry skin, and skin burning sensation.

Contraindications

Ivermectin should not be given to pregnant or lactating women, because it has been noted to cause birth defects in mice. Historical data have shown that microfilaricidal drugs, such as diethylcarbamazine citrate, might cause cutaneous and/or systemic reactions of varying severity (the Mazzotti reaction) and ophthalmologic reactions in patients with onchocerciasis. These reactions are probably due to allergic and inflammatory responses to the death of microfilariae. Patients treated with Stromectol for onchocerciasis may experience these reactions in addition to clinical adverse reactions possibly, probably, or definitely related to the drug itself.

Comment

Ivermectin is active against various life cycle stages of many but not all nematodes. It is active against the tissue microfilariae of *Onchocerca volvulus* but not against the adult form. The adult parasites reside in subcutaneous nodules which are infrequently palpable. Surgical excision of these nodules (nodulectomy) may be considered in the management of patients with onchocerciasis, since this procedure eliminates the microfilaria-producing adult parasites.

Ivermectin may be highly effective against *Strongyloides* and produces fewer side effects than thiabendazole. Compounds of the class bind selectively and with high affinity to glutamate-gated chloride ion channels which occur in invertebrate nerve and muscle cells. This leads to an increase in the permeability of the cell membrane to chloride ions with hyperpolarization of the nerve or muscle cell, resulting in paralysis and death of the parasite.

The drug is also effective against the microfilariae of *Wuchereria bancrofti*, *Brugia malayi*, and *Loa loa*. Rarely, patients with onchocerciasis who are also heavily infected with *L. loa* develop a serious or even fatal encephalopathy either spontaneously or following treatment with an effective microfilaricide. For these patients, the following adverse experiences have also been reported: back pain, conjunctival hemorrhage, dyspnea, urinary and/or fecal incontinence, difficulty in standing and/or walking, mental status changes, confusion, lethargy, stupor, or coma. This syndrome has been seen very rarely following the use of ivermectin; a cause-and-effect relationship has not been established. For individuals who warrant treatment with ivermectin for any reason and have had significant exposure to *L. loa*-endemic areas of West or Central Africa, pretreatment assessment for loiasis and careful posttreatment follow-up should be implemented.

Lumefantrine/Artemether (Coartem, Riamet) (Novartis)

Preparation

The drug is supplied as tablets: 20 mg to 120 mg (scored). This is an antimalarial drug, used for chloroquine-resistant *Plasmodium falciparum*.

Administration

This drug should be taken with food. Do not co-administer with CYP3A4 inducers (rifampin, carbamazepine, phenytoin, St. John's wort). It is not approved for prevention of malaria or for patients with severe or complicated *P. falciparum* malaria. It may prolong the QT interval; avoid with congenital QT interval prolongation (e.g., long QT syndrome) or any other clinical condition known to prolong the QT interval (e.g., history of symptomatic cardiac arrhythmias, clinically relevant bradycardia, severe cardiac disease), family history of congenital QT interval prolongation or sudden death, or known disturbances of electrolyte balance (e.g., hypokalemia, hypomagnesemia). Closely monitor patients who remain averse to food during treatment as risk of recrudescence may be greater; if recrudescent *P. falciparum* infection develops after treatment, treat the patient with a different antimalarial drug. Administer with caution in cases of severe hepatic/renal impairment.

Toxicity

The drug can cause headache, dizziness, anorexia, asthenia, pyrexia, chills, fatigue, arthralgia, myalgia, nausea and/or vomiting, abdominal pain, splenomegaly, hepatomegaly, and cough.

Comment

Artemether: Artemisinin derivative; antimalarial activity attributed to endoperoxide moiety. Lumefantrine: Antimalarial agent; not established. The drug is thought to inhibit the formation of β-hematin by forming a complex with hemin. Both artemether and lumefantrine inhibit nucleic acid and protein synthesis.

Malathion (Ovide) (Taro Pharmaceuticals)

Preparation

Ovide is supplied as a 0.5% aqueous emulsion and is used to treat human louse infestations, killing both lice and nits. Malathion is an organophosphate agent which acts as a pediculicide by inhibiting cholinesterase activity *in vivo*.

Administration

The drug is applied as a lotion to the skin or hair. It is placed on dry hair in a sufficient amount to thoroughly wet the hair. The hair is then allowed to dry naturally and shampooed after 8 to 12 h. It is then rinsed, and a fine comb is used to remove dead lice and nits. If lice are still present 7 to 9 days later, the drug should be reapplied.

Toxicity

Malathion may cause acute renal failure. Because the potential for transdermal absorption of malathion from Ovide lotion is not known at this time, strict adherence to the dosing instructions regarding its use in children, method of application, duration of exposure, and frequency of application is required.

Contraindications

The drug should not be given to individuals exposed to organophosphorous compounds or to infants or neonates. It may cause skin irritation. Because animal reproduction studies are not always predictive of human responses, this drug should be used (or handled) during pregnancy only if clearly needed. The safety and effectiveness of Ovide lotion in children younger than 6 years has not been established in well-controlled trials.

Mebendazole (Generics)

Preparation

The drug is supplied as 100-mg chewable tablets; it is a benzimidazole, broad-spectrum agent used to treat nematode infections. Mebendazole is indicated for the treatment of *Enterobius vermicularis* (pinworm), *Trichuris trichiura* (whipworm), *Ascaris lumbricoides* (common roundworm), *Ancylostoma duodenale* (common hookworm), and *Necator americanus* (American hookworm) in single or mixed infections. In humans, approximately 2% of the administered drug is excreted in urine and the remainder is excreted in the feces as unchanged drug or a primary metabolite. Mebendazole inhibits formation of worms' microtubules and causes worms' glucose depletion.

Administration

Tablets are chewable, but it may be necessary to pulverize them and mix them with food for administration to young children. The drug inhibits the formation of nematode microtubules and causes glucose depletion in the worms. Periodic assessment of the hematopoietic and hepatic system is advisable during prolonged therapy.

Toxicity

Abdominal pain and diarrhea occasionally occur, particularly with the expulsion of a large number of worms in children. Rash, urticaria, and angioedema have been observed on rare occasions. Very rare reports of convulsions have been documented.

Contraindications

The drug is teratogenic in rats, but the incidence of abortion and malformations in humans does not exceed the rate in the general population. The drug, however, is not recommended in pregnancy, particularly during the first trimester, unless the benefit justifies the potential risk to the fetus. It is also not recommended during lactation. In patients with severe hepatic disease, the drug should be used with caution. There is no evidence that mebendazole, even at high doses, is effective for treating hydatid disease. There have been rare reports of neutropenia and agranulocytosis when the drug was taken for prolonged periods and at dosages substantially above those recommended.

Mefloquine Hydrochloride (Generics)

Preparation

The drug is supplied as 250-mg tablets equivalent to 228 g of the free base; it is a synthetic 4-quinoline methanol compound structurally related to quinine. The bioavailability of the tablet formation compared with an oral solution was over 85%. The presence of food significantly enhances the rate and extent of absorption, leading to about a 40% increase in bioavailability. Mefloquine hydrochloride is used for the treatment of mild to moderate acute malaria caused by susceptible strains of *Plasmodium falciparum* and/or *P. vivax*. It is also used for prophylaxis of *P. falciparum* and *P. vivax* malaria infections, including prophylaxis of chloroquine-resistant strains of *P. falciparum*.

Administration

Tablets should not be ingested on an empty stomach and should be taken with at least 8 oz of water.

Toxicity

The most frequent side effects include nausea, vomiting, dizziness, diarrhea, abdominal pain, and headache. Severe seizures and delirium have been reported occasionally in roughly 1 in 200 to 1 in 1,300 patients treated for acute *P. falciparum* malaria. The drug can also potentiate dysrhythmias in patients taking beta blockers. Periodic evaluation of hepatic function should be performed during prolonged prophylaxis.

Contraindications

Use of mefloquine is contraindicated in patients with a known hypersensitivity to mefloquine or related compounds (e.g., quinine and quinidine). The drug should not be prescribed for prophylaxis in patients with active depression, a recent history of depression, generalized anxiety disorder, psychosis, schizophrenia, or other major psychiatric disorders, or in those with a history of convulsions. In patients with epilepsy, the drug may increase the risk of convulsions. The drug should be used with caution in patients with severe hepatic or renal dysfunction. During prophylactic use, if psychiatric symptoms such as acute anxiety, depression, restlessness, or confusion occur, these may be considered prodromal to a more serious event. In these cases, the drug must be withdrawn and an alternative medication should be substituted.

In case of life-threatening, serious, or overwhelming malaria infections with P. falciparum*, patients should be treated with an i.v. antimalarial drug. Following completion of i.v. treatment, mefloquine may be given to complete the course of therapy.*

Comment

Although its exact mechanism of action is not known, mefloquine is an antimalarial agent which acts as a blood schizonticide. The drug is thought to act by interfering with the digestion of hemoglobin during the erythrocytic stages of the life cycle. The drug has no activity against tissue schizonts or gametocytes. Strains of *P. falciparum* with decreased susceptibility to mefloquine can be selected *in vitro* or *in vivo*. Resistance of *P. falciparum* to mefloquine has been detected in areas of multidrug resistance in Southeast Asia. Increased incidences of resistance have also been reported in other parts of the world.

Strains of *P. falciparum* resistant to mefloquine have been detected. Mefloquine is indicated for the treatment of mild to moderate acute malaria caused by mefloquine-susceptible strains of *P. falciparum* (both chloroquine-susceptible and -resistant strains) or by *P. vivax*. However, patients with *P. vivax* malaria are at risk of relapse since mefloquine does not eliminate the exoerythrocytic parasites in the liver. Mefloquine is also indicated for the prophylaxis of *P. falciparum* and *P. vivax* malaria infections, including those caused by chloroquine-resistant strains of *P. falciparum*.

Mefloquine should be used during pregnancy only if the potential benefit justifies the potential risk to the fetus. Women of childbearing potential who are traveling to areas where malaria is endemic should be warned against becoming pregnant. Women of childbearing potential should also be advised to practice contraception during malaria prophylaxis with mefloquine and for up to 3 months thereafter. However, in the case of unplanned pregnancy, malaria chemoprophylaxis with mefloquine is not considered an indication for pregnancy termination. Because of the potential for serious adverse reactions in nursing infants from mefloquine, a decision should be made whether to discontinue treatment, taking into account the importance of the drug to the mother.

Melarsoprol (Mel-B) (CDC)

Preparation

Melarsoprol is supplied through the CDC Parasitic Disease Drug Service as a 3.6% solution in propylene glycol. It is used to treat African trypanosomiasis. The drug should be kept refrigerated. It is to be administered only in the hospital by or under the immediate supervision of a physician.

Administration

The drug should be given in propylene glycol as a slow i.v. infusion in the hospital. Care must be taken to avoid extravasation.

Toxicity

Abdominal pain, nausea, vomiting, and diarrhea are common. Reactive encephalopathy is not uncommon and is more likely to occur in debilitated patients and when high doses are used. The patient may also exhibit confusion, speech difficulties, restlessness, and sleep disorders. Myocardial damage, albuminuria, and hypertension have also been reported. A rare reaction is shock and subsequent death. Due to toxicity, the drug is usually reserved for the late stages of disease involving the central nervous system.

Rare side effects may include black, tarry stools; blood in urine or stools; changes in skin color of face; fainting; fast or irregular breathing; pinpoint red spots on skin; puffiness or swelling of the eyelids or around the eyes; shortness of breath; sores, ulcers, or white spots on lips or in mouth; sore throat; swollen and/or painful glands; tightness in chest; trouble in breathing; unusual bleeding or bruising; unusual tiredness or weakness; or wheezing.

Contraindications

Patients with impaired hepatic or renal function should not receive melarsoprol. Severe hemolytic reactions can occur in patients with G6PDH deficiency, and erythema nodosum may be induced in patients with leprosy. The drug should not be given during influenza epidemics. It may increase the chance of side effects in patients with fever and may increase the chance of side effects affecting the blood in patients with G6PDH deficiency.

Comment

Melarsoprol, an investigational drug, is an arsenical compound used for treating African trypanosomiasis (*Trypanosoma brucei gambiense*, *T. brucei rhodesiense*) with neurologic involvement or early African trypanosomiasis that is resistant to suramin or pentamidine. The drug apparently interferes with parasite energy generation and trophozoite multiplication.

Metronidazole (Flagyl, IV Flagyl) (Searle/Pfizer, Baxter)

Preparation

Flagyl is supplied as 375-mg tablets for oral administration and as 750-mg extended-release tablets (Flagyl ER); it is used in the treatment of amebiasis, giardiasis, trichomoniasis, and some helminth infections. It is also available in single-dose vials containing 500 mg of lyophilized powder or in 100-ml plastic containers containing a solution of 500 mg/100 ml or isotonic-buffered solution for parenteral injection. If metronidazole is being prescribed for trichomoniasis, sexual partners are often treated at the same time, even if they are asymptomatic.

Administration

Flagyl is usually given orally. When given i.v., it should be administered slowly as an intermittent or continuous infusion. Other drugs should not be added to the i.v. line during the infusion. Care must be taken to follow instructions for reconstitution of the solution, because neutralization with bicarbonate is necessary to bring the pH from 0.5–2 up to the neutral range. Administration i.v. can be used in cases of invasive amebiasis.

Toxicity

Reactions to therapy are common, especially when the drug is given in doses appropriate for treating amebiasis. The more common side effects include anorexia, nausea, vomiting, diarrhea, epigastric distress, and abdominal cramps. A metallic taste in the mouth is often reported. Headache, dizziness, and vertigo may also occur. Ataxia, paresthesias, insomnia, and irritability may also occur. A flattening of the T waves on an electrocardiogram may be evident, and rashes and urticaria have been reported. A moderate leukopenia occasionally occurs, but levels return to normal after completion of therapy. Oral and vaginal overgrowth of yeast cells may occur. In patients receiving high doses, dark urine has occurred; this finding may be due to a metabolite of the drug. Rare reactions include blood dyscrasias, dysuria, incontinence, cystitis, dyspareunia, and fever.

Contraindications

The drug should not be given to patients with a history of blood dyscrasia, active central nervous system disease, and/or known sensitivity to metronidazole. Doses should be reduced in patients with severe liver disease. The drug should not be used in pregnancy, especially in the first trimester, unless the benefits of treatment outweigh the potential hazard to the fetus. Consumption of alcohol should be avoided during the first days of treatment and for at least 3 days after the end of the treatment because severe vomiting, abdominal cramps, and flushing may occur. Other alcohol-containing preparations (for example, elixirs, cough syrups, and tonics) may also cause problems. These problems may last for at least a day after the drug has been discontinued. Leukocyte counts with differential blood counts are recommended before and after therapy. A good alternate for use during pregnancy is paromomycin.

Miltefosine (Impavido, Miltex) (Paladin, Canada) (CDC)

Preparation

The drug is given orally at 30 mg/kg twice a day; it has activity against *Leishmania* spp. It is not available within the United States. In India, it has been given at 2.5 mg/kg/day for 4 weeks, with good results for visceral leishmaniasis. Good activity has also been documented against *L. viannia panamensis*, with less activity against *L. mexicana mexicana* and even lower for *L. viannia braziliensis*. It is also used to treat granulomatous amebic encephalitis caused by *Acanthamoeba* spp.

Administration

The drug is given in two divided doses or a single dose orally for 28 days. It is available as 50-mg and 10-mg capsules.

Toxicity

Most patients tolerate therapy with few or no side effects. Nausea, vomiting, and diarrhea have been reported, and there have been isolated reports of dose-related motion sickness. Some patients have reversible hepatotoxicity and nephrotoxicity. Urea and creatinine levels usually return to normal by the end of the second week of therapy. Gastrointestinal symptoms could be serious in severely ill patients who are malnourished and dehydrated.

Contraindications

The drug should not be used during pregnancy or lactation.

Comment

The mechanism is not well defined, but apparently the drug interferes with cell-signaling pathways and membrane synthesis. It also induces apoptotic cell death. It is active against the extracellular promastigote and the intracellular amastigote forms of *Leishmania* spp.

Niclosamide (Yomesan, Niclocide) (Bayer, Germany)

Preparation

Niclosamide is available in 500-mg chewable tablets (chlorosalicylamide), which is effective against infections with tapeworms (*Taenia* spp., etc). The drug is no longer available in the United States. Its use is limited, and praziquantel is now more commonly used.

Administration

The drug is given orally; however, to prevent stomach upset, it is best taken after a light meal (for example, breakfast). Niclosamide tablets should be thoroughly chewed or crushed and then swallowed with a small amount of water. If this medicine is being given to a young child, the tablets should be crushed to a fine powder and mixed with a small amount of water to form a paste.

Toxicity

Most patients tolerate therapy with few or no side effects. Nausea, vomiting, and abdominal pain occur rarely, and there have been isolated reports of fever, dizziness, urticaria, irritability, headache, and edema of the arms.

Contraindications

Niclosamide should not be given to patients shown to be hypersensitive to the drug. Insufficient data are available for an assessment of the hazards of use of this drug during pregnancy. It is not recommended for pregnant women and children younger than 2 years.

Nifurtimox (Lampit) (Bayer HealthCare) (CDC)

Preparation

Nifurtimox is a nitrofuran and is supplied as 100-mg tablets through the CDC Parasitic Disease Drug Service; it is used in the treatment of acute Chagas' disease.

Administration

The drug is given orally. Tolerance for the drug decreases with age, and children generally can tolerate higher doses over a longer period than can adults.

Toxicity

Gastrointestinal symptoms are common and may include anorexia, weight loss, abdominal pain, nausea, and vomiting. Neuropsychiatric symptoms, including convulsions, headache, drowsiness, nervousness, vertigo, paresthesia, disorientation, and memory loss, are less common but may necessitate termination of therapy.

Contraindications

The drug should not be used in pregnant women or in children younger than 1 year. Alcohol, antibiotics, and digitalis may potentiate the side effects. It should be used with caution in elderly patients with a history of neurologic or psychiatric diseases or allergic skin reactions.

Comment

Nifurtimox, an investigational drug, is a nitrofurfurylidene derivative. Its action is apparently related to its ability to cause the production of toxic reduced products of oxygen such as superoxide, hydrogen peroxide, and hydroxyl radicals. Accumulation of these products within the parasites leads to membrane damage, enzyme inactivation, and possible inhibition of protein synthesis. Nifurtimox is used to treat acute, subacute, or early chronic Chagas' disease. Although only two cases of indigenous Chagas' disease have been reported from the United States, infections may be seen in laboratory workers, immigrants, and U.S. citizens returning from Latin America, such as Peace Corps volunteers, military personnel, and missionaries. Drinking alcoholic beverages while taking this medicine may cause some unwanted effects. Other alcohol-containing preparations (for example, elixirs, cough syrups, and tonics) may also cause problems. Therefore, the patient should not drink alcoholic beverages or ingest other alcohol-containing preparations while taking nifurtimox.

Nitazoxanide (Alinia) (Romark)

Preparation

Nitazoxanide is a relatively new synthetic drug with good efficacy against a number of intestinal protozoa and helminths. Alinia tablets contain 500 mg of nitazoxanide, and Alinia for oral suspension, after reconstitution, contains 100 mg nitazoxanide per 5 ml. Nitazoxanide and its metabolite, tizoxanide, are active *in vitro* in inhibiting the growth of sporozoites and oocysts of *Cryptosporidium* spp. and trophozoites of *Giardia lamblia*. Nitazoxanide may also be effective in the treatment of intestinal microsporidiosis with *Enterocytozoon bieneusi* and *Encephalitozoon intestinalis*, as well as ocular infections with *Vittaforma corneae* (see dosage information under *Giardia lamblia*). However, nitazoxanide was not shown to be superior to placebo for treatment of diarrhea caused by *Cryptosporidium parvum* in HIV-infected or immunodeficient patients.

Administration

The drug should be taken orally with food. Diabetic patients and their caregivers should be aware that the oral suspension contains 1.48 g of sucrose per 5 ml. Alinia for oral suspension should be used for pediatric patients younger than 11 years.

Toxicity

The most common adverse events reported were abdominal pain, diarrhea, headache, and nausea. Other reported side effects included weakness, fever, pain, chills, flu syndrome, dizziness, somnolence, insomnia, rash, and pruritus.

Contraindications

The pharmacokinetics of nitazoxanide in patients with compromised renal or hepatic function has not been studied. Therefore, nitazoxanide must be administered with caution to patients with hepatic and/or biliary disease, renal disease, and combined renal and hepatic disease. Nitazoxanide is highly bound to plasma protein; competition for binding sites could occur with other drugs such as warfarin. Based on limited safety data, this drug should not be used during pregnancy or lactation.

Comment

The antiprotozoal activity of nitazoxanide is thought to be due to interference with the pyruvate ferredoxin oxidoreductase (PFOR) enzyme-dependent electron transfer reaction, which is essential to anaerobic energy metabolism. Studies have shown that the PFOR enzyme from *G. lamblia* directly reduces nitazoxanide by transfer of electrons in the absence of ferredoxin. The DNA-derived PFOR protein sequence of *Cryptosporidium* spp. appears to be similar to that of *G. lamblia*. Interference with the PFOR enzyme-dependent electron transfer reaction may not be the only pathway by which nitazoxanide exhibits antiprotozoal activity.

Nitazoxanide therapy has also been given for intestinal microsporidiosis at a dose of 1,000 mg twice a day for 60 consecutive days. Three posttreatment fecal examinations, including PCR, conducted over 2 months following the end of the treatment with nitazoxanide did not reveal any microsporidial spores, and the patient continued normal bowel movements. Nitazoxanide has also been reported to be effective in cell culture against *E. intestinalis* and *V. corneae*.

Paromomycin (Generics) (Sun Pharma)

Preparation

Humatin is supplied as 250-mg capsules and a syrup with 125 mg per 5 ml; a broad-spectrum antibiotic, it is used to treat various intestinal protozoal infections, particularly acute and chronic intestinal amebiasis. The drug is poorly absorbed after oral administration, with almost 100% of the drug being recoverable in the stool. The drug is also prepared as a topical (*Leshcutan*) for the treatment of mucocutaneous leishmaniasis.

Administration

The drug is given orally with a full glass of water and should be taken with food.

Toxicity

Nausea, vomiting, abdominal cramps, and diarrhea have been reported, particularly in patients taking more than 3 g/day. Dizziness has also been reported. Assess for history of hypersensitivity to the drug, intestinal obstruction, and ulcerative lesions of the bowel.

Contraindications

The drug should not be used in patients with impaired renal function, intestinal obstruction, or ulcerative bowel lesions. Paromomycin and other aminoglycosides should be avoided in patients with myasthenia gravis. The drug should not be used during pregnancy or lactation.

Pentamidine Isethionate (Pentam 300, Nebupent) (APP Pharmaceuticals)

Preparation

Pentamidine isethionate is supplied as 300-mg vials for i.v. or i.m. administration. For inhalation, the vial contents are dissolved in sterile water and the inhalation solution is placed in a Respirgard II nebulizer. Saline solution must not be used to reconstitute the drug. Pentamidine isethionate is a toxic but highly effective drug used to treat the early stages of both types of African trypanosomiasis (*Trypanosoma brucei gambiense* and *T. brucei rhodesiense*). It does not cross the blood-brain barrier and is not effective in the treatment of the neurologic phases of the disease. It is also used to treat leishmaniasis and *Pneumocystis jirovecii* (now classified with the fungi) infection. The drug is also used to treat free-living amebae infections, such as granulomatous amebic encephalitis caused by *Acanthamoeba* spp., *Balamuthia mandrillaris*, and *Sappinia* sp.

Administration

Vial contents should be dissolved in sterile water for i.m. injection or in sterile water followed by sterile 5% glucose for i.v. administration. Pentamidine for inhalation should be administered for approximately 35 to 40 min at a rate of 5 to 7 liters/min.

Toxicity

Common side effects include hypotension, tachycardia, nausea, vomiting, and a metallic taste that occurs immediately after injection but subsides in 10 to 30 min. Hypoglycemia is occasionally seen from days 5 to 7 of therapy. Acute renal failure has occurred during the course of therapy; however, it is usually reversible in patients with normal renal function before therapy. Mild anemia, elevated liver transaminase levels, and leukopenia have been reported. Local pain and inflammation of the injection site are common, and sterile abscesses occasionally occur. Hypotension and profound shock have been reported after a single dose of the drug, and resuscitation equipment should always be readily available in the setting in which drug therapy is given. Occasional seizures and hallucinations have also been reported. Inhaled pentamidine can cause cough, bronchospasm, fatigue, bad taste in the mouth, shortness of breath, decreased appetite, dizziness, and rash. Pentamidine has also been associated with Stevens-Johnson syndrome.

Contraindications

Because pentamidine is generally used in life-threatening situations, there are no absolute contraindications to therapy. Careful observation of the patient is necessary because of the common side effects and severe drug reactions that may occur. Impaired renal function is frequent. Aerosol pentamidine should not be given with other drugs or given to patients with a history of anaphylactic reactions to inhaled or parenteral pentamidine. Some patients may develop a sudden, severe decrease in blood pressure after a dose of pentamidine. Pentamidine can decrease the white blood cell count, increasing the chance that the patient will contract certain infections. It can also lower the number of platelets, which are necessary for proper blood clotting. Both low and high blood sugar levels have also been reported. Unless the benefits outweigh the potential risks, this drug should not be used during pregnancy.

Comment

Although its mode of action remains unclear, its activity may be different for different parasites. Pentamidine (Lomidine) is used only for the early phase of the disease, since it does not cross the blood-brain barrier. It is active against *T. gambiense*, but it should not be used against *T. rhodesiense*, since primary resistance to it has been found in some areas. It should also not be used in areas where pentamidine has been widely employed for chemoprophylaxis, such as in the Democratic Republic of the Congo.

Permethrin (Nix [Insight Pharmaceuticals], Elimite [Prestium Pharma])

Preparation

Permethrin is supplied as a 1 or 5% cream. It is used to treat scabies (a skin infestation) and lice infestations of the head, body, and pubic area ("crabs"). Permethrin does not prevent these infestations.

Administration

The drug is available as a 1% (Nix) or 5% (Elimite) cream applied directly to hair or skin to treat lice or scabies, respectively.

If using the liquid, follow these steps: shampoo the hair using regular shampoo; thoroughly rinse and towel dry hair and scalp; allow hair to air dry for a few minutes; do not stand (or sit) in a shower or bathtub; lean over a sink to apply permethrin to the hair; shake the bottle of liquid well; thoroughly wet hair and scalp with the liquid. Cover the areas behind the ears and the back of the neck; keep permethrin on the hair for 10 minutes before rinsing it off thoroughly with water; dry hair with a clean towel; comb hair with a fine-tooth comb to remove nits (lice eggs and larvae); wash hands to remove the medication.

If using the cream, follow these steps: wash entire body or take a shower; thoroughly massage the cream into the skin over the entire body, from head to toes; leave the cream on for 8 to 14 h; wash the cream off after 8 to 14 h by taking another shower; if using product for head lice, wash combs and brushes with permethrin liquid and rinse them thoroughly with water to remove the drug.

Toxicity

Side effects are rare and include occasional burning, stinging, and numbness; increased pruritus; pain; edema; erythema; and rash.

Contraindications

The cream or lotion should not be applied near the eyes or mucous membranes. The drug may cause progressive motor neuron disease.

Polyhexamethylene Biguanide (Baquacil) (Zeneca)

Preparation

Baquacil is supplied as a 20% solution, which must be diluted with sterile saline to 0.02% for ophthalmic application. It is used to treat keratitis caused by *Acanthamoeba* spp. It is important to be cautious when using corticosteroids in patients with a previous history of *Acanthamoeba* keratitis (AK), even in the relatively distant past. Patients with AK should be warned regarding the risks of recurrence following presumed resolution and the need for retreatment.

Administration

Topical application is recommended at hourly intervals until clinical improvement is noted. Polyhexamethylene-biguanide is available through Leiter's Park Avenue Pharmacy, San Jose, CA (800-292-6773; www.leiterrx.com).

Toxicity

No information is available.

Contraindications

No information is available.

Comment

While this therapy inactivates the trophozoites and cysts in *Acanthamoeba* keratitis in the majority of patients (approximately 90%), there have been notable failures, particularly when patients present late with deep stromal infection. Since no single drug can be assumed to be effective against all amebae, a potential complication is the risk of activation of dormant cysts which form *in situ* in *Acanthamoeba* and *Balamuthia* infections and which can lead to relapse following apparently effective treatment. This is particularly true for *Acanthamoeba* keratitis, a non-opportunistic infection of the cornea, which responds well to treatment with chlorhexidine gluconate and polyhexamethylene biguanide in combination with propamidine isethionate (Brolene), hexamidine (Desomodine), or neomycin. In a large series of *Acanthamoeba* keratitis patients with a positive microbiologic diagnosis at presentation, nearly 5% developed recurrent episodes of corneal and scleral inflammation with viable *Acanthamoeba* in the cornea despite prolonged treatment with biguanides and/or diamidines.

Praziquantel (Biltricide) (Bayer)

Preparation

Praziquantel is supplied as 150-, 500-, and 600-mg scored tablets. It is a pyrazinoisoquinoline derivative and is a synthetic heterocyclic broad-spectrum anthelmintic agent effective against all schistosome species infecting humans, as well as most other trematodes and adult cestodes. However, it is not useful for treatment of nematode infections and is not effective in treating *Fasciola hepatica*. It has also been used in the treatment of cysticercosis.

Administration

Praziquantel is preferably taken during a meal, particularly one with a high carbohydrate content. After oral administration, over 80% of the drug is absorbed.

Toxicity

In general, the drug is well tolerated; side effects are usually mild. Reactions include malaise, headaches, dizziness, abdominal discomfort, nausea, vomiting, fever, and rarely urticaria. When it is used in high doses, as in the treatment of central nervous system cysticercosis, reactions that have been attributed to the death of the larvae can occur. These reactions include headache, peripheral neuropathy, seizures, fever, hypotension, and shock. Anaphylaxis has also been reported. Transient hyperglycemia lasting several months after therapy has also been reported. Patients are generally hospitalized during the initiation of therapy for cysticercosis because of the potential for serious reactions such as seizures and other neurologic sequelae related to an inflammatory response.

Contraindications

The drug induces drowsiness and dizziness and so should be used with caution in patients whose vocation requires mental alertness. If the drug is given to patients with ocular cysticercosis, parasite destruction may cause irreparable eye damage. Although studies involving high doses of praziquantel in pregnant animals have failed to show any harm to the fetus, there are no controlled studies of humans. The use of praziquantel in pregnant women and in children younger than 4 years has not been well studied, and both the risks and the benefits must be considered. Praziquantel does appear in human milk, and mothers should not breastfeed during treatment and for 72 h following treatment. Concomitant administration of rifampin should be avoided.

Comment

Praziquantel causes ultrastructural changes in the helminth tegument, causing increased permeability to calcium ions. It works by causing severe spasms and paralysis of the worms' muscles. Some kinds of worms are then passed in the stool. However, the patient may not notice them since they are sometimes completely destroyed in the intestine.

Primaquine Phosphate (Sanofi-Aventis)

Preparation

The drug is supplied in tablets containing 26.3 mg of primaquine phosphate, equivalent to 15 mg of salt. It is an antimalarial agent especially effective against *Plasmodium vivax* exoerythrocytic forms, terminating relapsing vivax malaria; it is usually administered with chloroquine. It is also effective against gametocytes of *P. falciparum*.

Administration

Tablets have a bitter taste and may be crushed and added to a sweet liquid or fruit to make them more palatable.

Toxicity

Patients may experience abdominal pain, cramps, or epigastric distress. High doses may result in methemoglobinemia and cyanosis. Granulocytopenia and granulocytosis, hypertension, and arrhythmia are rare. Hemolysis occurs in individuals with G6PDH deficiency.

Contraindications

The drug should not be used in patients with depressed blood counts resulting from other illnesses or concurrently with drugs, such as quinacrine, that have the potential to cause hemolysis or bone marrow depression. Because primaquine phosphate can cause hemolytic anemia, patients should be screened for G6PDH deficiency, which is most common in African, Asian, and Mediterranean people. Administration of other bone marrow depressants as hemolytic agents should be avoided. The drug should not be prescribed during pregnancy.

Propamidine Isethionate (Brolene) (Aventis, Canada)

Preparation

Brolene is provided as a 0.1% solution. It is a local anti-infective agent that is used to treat keratitis caused by *Acanthamoeba* spp., but it is not available in the United States.

Administration

Brolene is administered topically each hour for the first few days and every few hours thereafter for a minimum course of 1 month.

Toxicity

The drug may cause keratopathy; this condition is reversible but may be confused with persistent or recurrent infection.

Contraindications

No information is available.

Comment

Treatment of *Acanthamoeba* keratitis is difficult due to the organism's ability to encyst. Effective medications include topical polyhexamethylene biguanide, propamidine isethionate (Brolene), chlorhexidine digluconate 0.02%, polymixin B, neomycin, and clortrimazole 1%. In one series of 10 patients, the combination of Brolene and polyhexamethylene biguanide successfully cured all cases of *Acanthamoeba* keratitis. Cautious introduction of topical steroids along with antiamebic therapy helped resolve the inflammation and provided symptomatic relief.

Pyrantel Pamoate (Pin-X, Reese's Pinworm Medicine) (Quartz Specialty Pharmaceuticals, Reese)

Preparation

Liquid medication is supplied in 60-ml bottles containing 50 mg of pyrantel base per ml or as tablets containing 125 mg of base and is used to treat a number of different nematode infections. However, it is associated with more side effects and is being replaced with the benzimidazoles, which are more effective.

Administration

Pyrantel pamoate may be taken with food, milk, or juice.

Toxicity

Reactions are not frequently encountered, but when they do occur, they involve primarily the gastrointestinal system. They include anorexia, nausea, vomiting, abdominal pain or cramps, diarrhea and tenesmus, and transient elevations of the transaminase enzyme levels.

Contraindications

Studies of pregnant animals have failed to show any harm to the fetus, but there is no experience with pregnant humans. There are few published data on the use of the drug in children younger than 2 years. The risks and benefits of treatment in these patients should be weighed. The drug should be used with caution in patients with liver dysfunction. Its anthelmintic effect may be antagonized by piperazine.

Comment

The drug is a neuromuscular blocking agent, resulting in spastic paralysis of the adult worms. Excellent results are obtained when treating patients with ascariasis, hookworm, and pinworm infections. While there is some activity against *Trichostrongylus,* the drug is not active against *Trichuris trichiura.*

Pyrethrin with Piperonyl Butoxide (Rid) (Bayer, Others)

Preparation

Rid is an insecticide mixture of permethrin and piperonyl butoxide, which is used as a synergist and also to treat human louse infestations.

Administration

Rid is applied topically as a shampoo to the affected area after wetting. After application, it should be left for 10 min and then rinsed thoroughly. Hair should be combed with a fine-tooth comb to remove dead lice and nits.

Toxicity

Rid may cause allergic reactions in individuals allergic to ragweed.

Contraindications

The drug should not be used near eyes or mucous membranes.

Pyrimethamine (Daraprim) (Amedra)

Preparation

Daraprim is supplied as 25-mg tablets; it is a potent folic acid antagonist used as an antimalarial agent and in treating toxoplasmosis and several other parasitic infections. Dosages for treating toxoplasmosis approach the toxic level. Daraprim should be kept away from children and infants since they are extremely susceptible to adverse effects from an overdose and deaths have been reported.

Administration

The drug may be pulverized and mixed with sweet liquid or fruit juice. Concurrent administration of folinic acid is strongly recommended for all patients. Daraprim is indicated for the treatment of toxoplasmosis when used conjointly with a sulfonamide, providing synergy with this combination approach. Although Daraprim is used to treat acute malaria, it should not be used alone for this purpose. It is also used for chemoprophylaxis of malaria; however, there is widespread resistance throughout the world.

Toxicity

Gastrointestinal complaints (anorexia, nausea, vomiting, diarrhea, and abdominal pain and tenderness) are not uncommon. Occasional elevation of the glutamic-oxaloacetic transaminase level in serum has been reported, as have skin rashes, headache, dizziness, drowsiness, and insomnia. For patients with toxoplasmosis being treated with high doses, periodic complete blood counts, including platelet counts, are recommended. Folic acid supplementation may be necessary if the counts are depressed. Hypersensitivity reactions, occasionally severe (Stevens-Johnson syndrome, toxic epidermal necrolysis, erythema multiforme, and anaphylaxis), can occur, particularly when the drug is administered concomitantly with a sulfonamide.

Contraindications

The drug should not be used in pregnancy, and determination of human chorionic gonadotropin levels is recommended before initiation of treatment for toxoplasmosis. Caution is recommended for patients with seizure disorders and impaired hepatic or renal function. Daraprim is also contraindicated for patients with documented megaloblastic anemia due to folate deficiency.

Comment

Pyrimethamine acts against the asexual erythrocytic stage of the *Plasmodium* spp. by inhibiting the enzyme dihydrofolate reductase. The drug does not destroy gametocytes but instead arrests sporogony in the mosquito. Although the drug is active against *P. falciparum*, resistance occurs fairly rapidly and limits its use as a single agent. Therefore, the drug is often combined with a sulfonamide or sulfone, which provides sequential, synergistic inhibition of the folate biosynthesis pathway. This inhibition of folic acid biosynthesis prevents DNA replication in the parasite. Pyrimethamine is also used in combination with sulfadiazine for treating toxoplasmosis.

Quinidine Gluconate (Generics)

Preparation

Quinidine gluconate is supplied as a solution containing 80 mg/ml for injection and is used to treat severe malaria.

Administration

The drug is given i.v. in normal saline by slow infusion; 800 mg is infused in 40 ml of 5% glucose at a rate of 1 ml/min. Avoid grapefruit juice during administration.

Toxicity

Quinidine causes gastrointestinal irritation, with nausea, vomiting, and diarrhea. Hypersensitivity may occur. Other side effects that have been reported include blurred vision, headache, belly pain, and ringing in the ears and temporary loss of hearing. Prolongation of the QT interval as indicated by an electrocardiogram, ventricular arrhythmia, hypotension, and hypoglycemia can result from the use of this drug at treatment doses. Rapid infusion can cause peripheral vascular collapse and severe hypotension.

Contraindications

The drug may induce hypotension, granulomatous hepatitis, and a lupus-like syndrome. Use should be avoided for patients with myasthenia gravis, acute infections with fever, previous hypersensitivity to quinidine, and cardiac abnormalities.

Quinine Sulfate or Quinine Dihydrochloride (Many Manufacturers)

Preparation

Quinine sulfate is supplied as 3-grain (186-mg) or 6-grain (372-mg) capsules or tablets. Quinine dihydrochloride comes in 2-ml ampoules containing 300 mg/ml (not available in the United States). It is used to treat malaria and is important in areas where i.v. quinine is not available. It is the dextrorotary optical isomer of quinine. It has also been used in the treatment of babesiosis.

Administration

The oral medication is extremely bitter and may be better tolerated if mixed with sweet liquid, fruit, or cereal. For i.v. administration, medication should be diluted in normal saline at 0.5 mg/ml and administered at 1 ml/min every 8 h.

Toxicity

Mild symptoms are common and generally consist of tinnitus, headache, nausea, and disturbed vision. More severe reactions are related to inability to excrete the drug normally and to high doses. These reactions include decreased hearing, blurred vision, photophobia, diplopia, night blindness, scotomata (blind spots), mydriasis (pupil dilation), vomiting, abdominal pain, diarrhea, cutaneous flushing, sweating, rashes, facial angioedema, confusion, apprehension, excitement, delirium, and syncope.

Contraindications

Rare reactions include renal failure, acute hemolysis, hypoprothrombinemia, purpura, agranulocytosis, asthma, and ventricular tachycardia. After one dose, an idiosyncratic hypersensitivity reaction consisting of flushing, pruritus, skin rash, fever, gastric distress, dyspnea, tinnitus, and visual impairment may occur. Massive hemolysis and hemoglobinuria occasionally occur during the treatment of falciparum malaria. Quinine may aggravate the symptoms of myasthenia gravis.

Spiramycin (Rovamycine) (Sanofi-Aventis)

Preparation

Rovamycine is supplied as a tablet or in solution and is a macrolide antibiotic similar to leucomycin. This drug has been tried in the treatment of cryptosporidiosis and toxoplasmosis; it is available only from the manufacturer.

Administration

Spiramycin is given orally on an empty stomach or by i.v. infusion.

Toxicity

Rovamycine can cause gastrointestinal disturbances and occasional allergic reactions. More rare side effects have included bloody stools, chest pain, fever, heartburn, irregular heartbeat, nausea, recurrent fainting, stomach pain and tenderness, vomiting, and yellow eyes or skin.

Contraindications

The drug should not be given to patients with impaired liver function.

Stibogluconate Sodium (Pentostam, Solustibosan) (GlaxoSmithKline) (CDC)

Preparation

Stibogluconate sodium is available through the CDC Parasitic Disease Drug Service as a 33% solution containing 100 mg of pentavalent antimony per ml; it is used to treat leishmaniasis.

Administration

The drug is given intramuscularly or by careful, slow i.v. infusion.

Toxicity

Side effects are common and include nausea, vomiting, severe coughing, and itching. Pneumonitis, arthralgias, myalgias, bradycardia, electrocardiogram changes (T-wave depressions, increased O-T interval, and fusion of the S-T segment and T wave), abnormal liver function, headache, and mild rash also occur. Less common problems are hepatitis, hemolytic anemia, thrombocytopenia, and anaphylaxis associated with urticaria, laryngeal edema, and visceral collagens.

Contraindications

The drug should not be used in patients with myocarditis, hepatitis, liver disease, or concurrent bacterial and viral infections. Treatment should be stopped if there is progressive proteinuria, severe arthralgias, or rash. More severe reactions may include leukopenia, agranulocytosis, and electrocardiographic changes.

Comment

Pentostam (sodium stibogluconate; sodium antimony gluconate) is a pentavalent antimony compound that is used to treat all forms of leishmaniasis (cutaneous, mucocutaneous, and visceral). This drug is a well-established antileishmanial agent that has been in use for some time. It is thought to inhibit glycolysis enzymes within the organisms.

Suramin Sodium (Germanin) (Bayer, Germany) (CDC)

Preparation

Suramin sodium is available through the CDC Parasitic Disease Drug Service as ampoules containing 1.0 g of powder and is a complex derivative of urea used to treat African trypanosomiasis.

Administration

A 10% solution must be prepared and used within 30 min of preparation as a slow i.v. infusion.

Toxicity

Immediate nausea, vomiting, loss of consciousness, and seizure may occur if the full i.v. dose is given to sensitive individuals. A test dose is recommended. Proteinuria is commonly seen during therapy, but it is not a parameter used to monitor therapy unless other renal function studies are abnormal. Fever is also common but is usually low grade. Rashes, localized edema, and pruritus may occur. Blepharitis, conjunctivitis, photophobia, and excessive lacrimation may occur during treatment. Kidney failure, blood dyscrasias (including pancytopenia), shock, and optic atrophy have also been reported.

Contraindications

The drug should be administered under close medical supervision and should not be used in pregnant women or in patients with hepatic or renal insufficiency. It should be used with caution in children younger than 6 years. It should not be used alone to treat African trypanosomiasis of the central nervous system.

Comment

Suramin was introduced in 1920 for the treatment of African trypanosomiasis (sleeping sickness). It is considered the drug of choice for treatment of early African trypanosomiasis with *Trypanosoma brucei rhodesiense* when the central nervous system is not involved. Pentamidine is thought to be more effective than suramin for treating early African trypanosomiasis caused by *T. brucei gambiense*. The mechanism of action of suramin is thought to be through inhibition of enzymes associated with protein synthesis and DNA metabolism.

Thiabendazole (Mintezol) (Merck)

Preparation

Mintezol is supplied as a flavored suspension containing 125 or 250 mg/5 ml, as pediatric drops containing 100 mg/ml, and as 500-mg chewable tablets. Thiabendazole is a benzimidazole that is used to treat a number of nematode infections, including strongyloidiasis, cutaneous and visceral larva migrans, trichinosis, and other intestinal roundworms. However, other drugs have become replacements for thiabendazole.

Administration

The drug is given orally, preferably after a meal; tablets should be chewed before being swallowed.

Toxicity

Common side effects are anorexia, vomiting, and dizziness. Less frequently, diarrhea, epigastric pain, pruritus, drowsiness, lethargy, and headache occur. Side effects include Stevens-Johnson syndrome, tinnitus, visual disturbance, hypotension, perianal rash, transient rises in transaminase enzyme levels, cholestasis, parenchymal liver damage, hyperglycemia, and hematuria. Treatment may cause migration of *Ascaris* organisms to the esophagus, mouth, and nose.

Contraindications

Patients with known hypersensitivity or with renal or hepatic impairment should not use thiabendazole. The drug causes dizziness and drowsiness and should not be used by patients whose vocation requires mental alertness. It is also contraindicated as prophylaxis for pinworm infections; susceptible worm infections should be confirmed by laboratory testing prior to drug use. Due to a lack of safety data, it should be used during pregnancy and lactation only if the potential benefit justifies the potential risk to the fetus.

Comment

Thiabendazole blocks glucose uptake, depletes glucose stores, and interferes with mictotubule aggregates. It also inhibits the fumarate-reductase system of helminths. However, administration of thiabendazole has been associated with side effects, and it has been replaced by other anthelmintic agents.

Tinidazole (Tindamax) (Mission Pharmaceuticals)

Preparation

Tinidazole is supplied as 150-, 200-, 300-, and 500-mg and 1-g tablets or as an oral suspension of 200 mg/ml. This drug is a synthetic nitroimidazole used to treat amebiasis and giardiasis.

Tindamax oral tablets are indicated for the treatment of trichomoniasis caused by *Trichomonas vaginalis* in both female and male patients. The organism should be identified by appropriate diagnostic procedures. Because trichomoniasis is a sexually transmitted disease with potentially serious sequelae, partners of infected patients should be treated simultaneously in order to prevent reinfection. Tindamax oral tablets are indicated for the treatment of giardiasis caused by *Giardia lamblia* in both adults and pediatric patients older than 3 years. Tindamax oral tablets are indicated for the treatment of intestinal amebiasis and amebic liver abscess caused by *Entamoeba histolytica* in both adults and pediatric patients older than 3 years. It is not indicated in the treatment of asymptomatic cyst passage.

Administration

Tinidazole is given orally with or after meals. After oral administration, it is rapidly and completely absorbed. Alcoholic beverages should be avoided while taking Tindamax and for 3 days afterward.

Toxicity

Tinidazole can cause nausea, vomiting, metallic taste, and rash. Convulsive seizures and peripheral neuropathy, the latter characterized mainly by numbness or paresthesia of an extremity, have been reported to occur in patients treated with nitroimidazole drugs including tinidazole and metronidazole. The appearance of abnormal neurologic signs demands the prompt discontinuation of Tindamax therapy. Tinidazole should be administered with caution to patients with central nervous system diseases or those with evidence of or history of blood dyscrasia.

Contraindications

As with other nitroimidazole derivatives, tinidazole may enhance the effect of warfarin and other coumarin anticoagulants, resulting in a prolongation of the prothrombin time. Alcoholic beverages and preparations containing ethanol or propylene glycol should be avoided during tinidazole therapy and for 3 days afterward because abdominal cramps, nausea, vomiting, headaches, and flushing may occur. Psychotic reactions have occurred in alcoholic patients using metronidazole and disulfiram concurrently. Because animal reproduction studies are not always predictive of the human response and because there is some evidence of mutagenic potential, the use of tinidazole during pregnancy requires that the potential benefits of the drug be weighed against the possible risks to both the mother and the fetus. Tinidazole is excreted in breast milk in concentrations similar to those seen in serum. It can be detected in breast milk for up to 72 h following administration. Interruption of breast-feeding is recommended during tinidazole therapy and for 3 days following the last dose.

Comment

The nitro group of tinidazole is reduced by cell extracts of *Trichomonas*. The free nitro radical generated as a result of this reduction may be responsible for the antiprotozoal activity. The mechanism by which tinidazole exhibits activity against *Giardia* and *Entamoeba* species is not known. Approximately 38% of *T. vaginalis* isolates with reduced susceptibility to metronidazole also show reduced susceptibility to tinidazole *in vitro*. The clinical significance of such an effect is not known.

Tinidazole, like metronidazole, may interfere with certain types of determinations of serum chemistry values, such as aspartate aminotransferase, alanine aminotransferase, lactate dehydrogenase, triglyceride, and hexokinase glucose levels.

Triclabendazole (Egaten) (Novartis)

Preparation

Triclabendazole is used in veterinary practice and is also being used to treat human infections with liver and lung flukes; it the drug of choice for treating infections with *Fasciola hepatica*. The drug is not available in the United States.

Administration

Egaten is given orally after a meal as a single or split dose of 10 mg/kg. A dose of 20 mg/kg is safe and effective for patients with acute fascioliasis when a single dose has failed to cure them.

Toxicity

Triclabendazole can cause abdominal pain; however, most studies reported no side effects. The tolerance of triclabendazole is considered excellent. Side effects include brief episodes of upper abdominal pain and slight fever and some mild and limited disturbances in liver function. These effects may be due to the paralysis and/or death of the flukes, resulting in the release of antigens or toxic products and the partial blockage of the bile ducts. Similar findings have been reported in various preliminary studies: triclabendazole has been reported to decrease parasite motility, but the exact mode of action of this drug is unknown. Some patients may require a second course of therapy.

Contraindications

Use of this drug may cause secondary cholangitis due to worm destruction. Triclabendazole has been reported to be nonmutagenic and nonteratogenic.

Appendixes

Although common names are frequently used to describe parasitic organisms, these names may represent different parasites in different parts of the world. To eliminate these problems, a binomial system of nomenclature is used in which the scientific name consists of the genus and species. On the basis of life histories and morphology, systems of classification have been developed to indicate the relationships among the various parasite species.

Parasites of humans are classified in five major subdivisions. These include the Protozoa (amebae, flagellates, ciliates, sporozoans, coccidia), the Platyhelminthes or flatworms (cestodes and trematodes), the Acanthocephala or thorny-headed worms, the Nematoda or roundworms, and the Arthropoda (insects, spiders, mites, ticks, etc.). Information on the Protozoa, Nematoda, Platyhelminthes, and Arthropoda is presented in Appendix 1, Table A1.1. This classification scheme is designed to provide some order and meaning to a widely divergent group of organisms. No attempt has been made to include every possible organism, but only those that are considered to be clinically relevant in the context of human parasitology. It is hoped this information will provide some insight into the parasite groupings, thus leading to a better understanding of organism morphology, parasitic infections, and the appropriate clinical diagnostic approach.

Data on distribution of various parasites are found in Tables A1.2 through A1.7; these tables are from Markell EK, Voge M, John DT, *Medical Parasitology*, 6th ed, WB Saunders Co, Philadelphia, PA, 1986. Diagnostic clinical review information is seen in Tables A1.8 through A1.16. Tables A1.17 through A1.20 contain information on stool ordering, collection, the ova and parasite examination, and laboratory test report comments. Table A1.21 provides information on the estimated prevalence of parasitic diseases worldwide.

Flowcharts for various diagnostic kits are seen in Appendix 2. Appendix 3 presents common problems in parasite identification, and Sheets A4.1 through A4.3 are examples of quality control recording sheets. Source information for diagnostic products and teaching materials is provided in Appendix 5. General references, a list of relevant journals and periodicals, and abstracts and bibliographic sources are provided for the reader in Appendix 6.

Appendix 7 contains information that has been published just months prior to final publication of the book. This synopsis of very recent, "late-breaking" publications can assist the reader in having access to the latest information available. I encourage everyone to review this section as they read various chapters throughout the book. Appendix 8 covers the currently approved molecular panels, some of which contain human clinically relevant parasites. Appendix 9 includes the most frequently asked questions for all areas of human parasitology; this section is very comprehensive and represents questions that have been asked by practicing microbiologists and other users of the book. Appendix 10 includes CPT codes that can be used for diagnostic methods for parasitology recovery and diagnosis.

It is hoped that the extensive information contained in the various appendix sections will be valuable to the reader and will serve as a comprehensive reference overall. I'm indebted to all of the readers who provided various types of input to help improve this sixth edition of *Diagnostic Medical Parasitology*.

APPENDIX 1

Information Tables

TABLE A1.1 Classification of human parasites

- **I. Protozoa**
  - 1. **Intestinal amebae**
    - *Entamoeba histolytica*
    - *Entamoeba dispar*[a]
    - *Entamoeba moshkovskii*
    - *Entamoeba bangladeshi*
    - *Entamoeba hartmanni*
    - *Entamoeba coli*
    - *Entamoeba polecki*
    - *Endolimax nana*
    - *Iodamoeba bütschlii*
    - *Blastocystis* spp.
  - 2. **Intestinal flagellates**
    - *Giardia lamblia*[b]
    - *Chilomastix mesnili*
    - *Dientamoeba fragilis*
    - *Pentatrichomonas hominis*
    - *Enteromonas hominis*
    - *Retortamonas intestinalis*
  - 3. **Intestinal ciliates**
    - *Balantidium coli*
  - 4. **Intestinal coccidia and microsporidia**
    - *Cryptosporidium parvum*
    - *Cryptosporidium hominis*
    - *Cryptosporidium* spp.
    - *Cyclospora cayetanensis*
    - *Cystoisospora belli*
    - *Sarcocystis hominis*
    - *Sarcocystis suihominis*
    - Microsporidia
      - *Enterocytozoon bieneusi*
      - *Encephalitozoon* (*Septata*) *intestinalis*
  - 5. **Sporozoa and flagellates from blood and tissue**
    - **Sporozoa (causing malaria and babesiosis)**
      - *Plasmodium vivax*
      - *Plasmodium ovale*
      - *Plasmodium malariae*
      - *Plasmodium falciparum*
      - *Plasmodium knowlesi*
      - *Babesia* spp.
    - **Flagellates (leishmaniae and trypanosomes)**
    - Old World *Leishmania* species
      - *Leishmania* (*Leishmania*) *tropica*
      - *Leishmania* (*Leishmania*) *major*
      - *Leishmania* (*Leishmania*) *aethiopica*
      - *Leishmania* (*Leishmania*) *donovani*
      - *Leishmania* (*Leishmania*) *archibaldi*
      - *Leishmania* (*Leishmania*) *infantum*
    - New World *Leishmania* species
      - *Leishmania* (*Leishmania*) *mexicana*
      - *Leishmania* (*Leishmania*) *amazonensis*
      - *Leishmania* (*Leishmania*) *pifanoi*
      - *Leishmania* (*Leishmania*) *garnhami*
      - *Leishmania* (*Leishmania*) *venezuelensis*
      - *Leishmania* (*Leishmania*) *chagasi*
      - *Leishmania* (*Viannia*) *braziliensis*
      - *Leishmania* (*Viannia*) *colombiensis*
      - *Leishmania* (*Viannia*) *guyanensis*
      - *Leishmania* (*Viannia*) *lainsoni*
      - *Leishmania* (*Viannia*) *naiffi*
      - *Leishmania* (*Viannia*) *panamensis*
      - *Leishmania* (*Viannia*) *peruviana*
      - *Leishmania* (*Viannia*) *shawi*
    - Old World *Trypanosoma* species
      - *Trypanosoma brucei gambiense*

(continued)

TABLE A1.1 *(continued)*

- *Trypanosoma brucei rhodesiense*
- New World *Trypanosoma* species
  - *Trypanosoma cruzi*
  - *Trypanosoma rangeli*

6. **Amebae and flagellates from other body sites**
   - **Amebae**
     - *Naegleria fowleri*
     - *Sappinia diploidea*
     - *Acanthamoeba* spp.
     - *Hartmanella* spp.
     - *Balamuthia mandrillaris*
     - *Entamoeba gingivalis*
   - **Flagellates**
     - *Trichomonas vaginalis*
     - *Trichomonas tenax*
7. **Coccidia, sporozoa, and microsporidia from other body sites**
   - **Coccidia**
     - *Toxoplasma gondii*
   - **Microsporidia**
     - *Nosema ocularum*
     - *Pleistophora* spp.
     - *Pleistophora ronneafiei*
     - *Trachipleistophora hominis*
     - *Trachipleistophora anthropophthera*
     - *Anncaliia vesicularum*
     - *Anncaliia* (*Brachiola*) *algerae*
     - *Anncaliia* (*Brachiola*) *connori*
     - *Encephalitozoon cuniculi*
     - *Encephalitozoon* (*Septata*) *intestinalis*
     - *Encephalitozoon hellem*
     - *Enterocytozoon bieneusi*
     - *Vittaforma corneae* (*Nosema corneum*)
     - *Microsporidium*[c]

II. Nematodes (roundworms)

1. **Intestinal**
   - *Ascaris lumbricoides*
   - *Enterobius vermicularis*
   - *Ancylostoma duodenale*
   - *Necator americanus*
   - *Strongyloides stercoralis*
   - *Strongyloides fuelleborni*
   - *Trichostrongylus colubriformis*
   - *Trichostrongylus orientalis*
   - *Trichostrongylus* spp.
   - *Trichuris trichiura*
   - *Capillaria philippinensis*
2. **Tissue**
   - *Trichinella spiralis*
   - *Trichinella* spp. (*T. britovi*, *T. murrelli*, *T. nativa*, *T. nelsoni*, *T. papuae*, *T. pseudospiralis*, *T. zimbabwensis*)
   - *Toxocara canis* and *Toxocara cati* (visceral and ocular larva migrans)
   - *Ancylostoma braziliense* and *Ancylostoma caninum* (cutaneous larva migrans)
   - *Dracunculus medinensis*
   - *Angiostrongylus cantonensis*
   - *Angiostrongylus costaricensis*
   - *Gnathostoma spinigerum*
   - *Anisakis* spp. (larvae from saltwater fish)
   - *Phocanema* spp. (larvae from saltwater fish)
   - *Contracaecum* spp. (larvae from saltwater fish)
   - *Hysterothylacium*
   - *Porrocaecum* spp.
   - *Capillaria hepatica*
   - *Thelazia* spp.
   - *Ternidens diminutus*
3. **Blood and tissues (filarial worms)**
   - *Wuchereria bancrofti*
   - *Brugia malayi*
   - *Brugia timori*
   - *Loa loa*
   - *Onchocerca volvulus*
   - *Mansonella ozzardi*
   - *Mansonella streptocerca*
   - *Mansonella perstans*
   - *Dirofilaria immitis* (usually found in lung lesions, eyes; in dogs, heartworm)
   - *Dirofilaria* spp. (may be found in subcutaneous nodules)

III. Cestodes (tapeworms)

1. **Intestinal**
   - *Diphyllobothrium latum*
   - *Diplogonoporus* spp.
   - *Dipylidium caninum*
   - *Hymenolepis nana*
   - *Hymenolepis diminuta*
   - *Taenia solium*
   - *Taenia saginata*
   - *Taenia asiatica*
2. **Tissue (larval forms)**
   - *Taenia solium*
   - *Echinococcus granulosus*
   - *Echinococcus multilocularis*
   - *Echinococcus vogeli*
   - *Echinococcus oligarthrus*
   - *Multiceps multiceps*
   - *Spirometra mansonoides*
   - *Diphyllobothrium* spp.

IV. Trematodes (flukes)

1. **Intestinal**
   - *Fasciolopsis buski*
   - *Echinostoma ilocanum*
   - *Echinochasmus perfoliatus*
   - *Heterophyes heterophyes*
   - *Metagonimus yokogawai*
   - *Gastrodiscoides hominis*
   - *Phaneropsolus bonnei*
   - *Prosthodendrium molenkempi*
   - *Spelotrema brevicaeca*
   - *Plagiorchis* spp.
   - *Neodiplostomum seoulense*
2. **Liver and lung**
   - *Clonorchis* (*Opisthorchis*) *sinensis*
   - *Opisthorchis viverrini*
   - *Opisthorchis felineus*
   - *Dicrocoelium dendriticum*

(continued)

TABLE A1.1 Classification of human parasites *(continued)*

- *Fasciola hepatica*
- *Fasciola gigantica*
- *Metorchis conjunctus*
- *Paragonimus westermani*
- *Paragonimus kellicotti*
- *Paragonimus africanus*
- *Paragonimus uterobilateralis*
- *Paragonimus miyazakii*
- *Paragonimus mexicanus*
- *Paragonimus caliensis*

3. **Blood**
    - *Schistosoma mansoni*
    - *Schistosoma haematobium*
    - *Schistosoma japonicum*
    - *Schistosoma intercalatum*
    - *Schistosoma mekongi*
    - *Schistosoma malayi*
    - *Schistosoma mattheei*

V. Pentastomids (tongue worms); *see* Arthropods, below

Tissue (larval forms)
- *Armillifer* spp.
- *Linguatula serrata*
- *Sebekia* spp.

Nasopharyngeal
- *Armillifer* spp.
- *Linguatula serrata*

VI. Acanthocephalans (thorny-headed worms)

Intestine
- *Macracanthorhynchus hirudinaceus*
- *Moniliformis moniliformis*

VII. Arthropods

1. **Arachnida**
    - Scorpions
    - Spiders (black widow, brown recluse)
    - Ticks (*Dermacentor*, *Ixodes*, *Argas*, and *Ornithodoros* spp.)
    - Mites (*Sarcoptes* spp.)
2. **Crustacea**
    - Copepods (*Cyclops* spp.)
    - Crayfish, lobsters, and crabs
3. **Pentastomida**
    - Tongue worms
4. **Diplopoda**
    - Millipedes
5. **Chilopoda**
    - Centipedes
6. **Insecta**
    - Phthiraptera (sucking lice [*Pediculus* and *Phthirus* spp.])
    - Blattaria (cockroaches)
    - Hemiptera (true bugs [*Triatoma* spp.])
    - Coleoptera (beetles)
    - Hymenoptera (bees, wasps, etc.)
    - Lepidoptera (butterflies, caterpillars, moths, etc.)
    - Diptera (flies, mosquitoes, gnats, and midges [*Phlebotomus*, *Aedes*, *Anopheles*, *Glossina*, *Simulium* spp., etc.])
    - Siphonaptera (fleas [*Pulex* and *Xenopsylla* spp., etc.])

---

[a] The name *Entamoeba histolytica* is used to designate the true pathogen, while the name *E. dispar* is now being used to designate the nonpathogen. However, unless trophozoites containing ingested red blood cells (*E. histolytica*) are seen, the two organisms cannot be differentiated on the basis of morphology seen in permanent stained smears of fecal specimens. Fecal immunoassays are available for detecting the *Entamoeba histolytica*/*E. dispar* group or for differentiating between the two species. *E. moshkovskii* and *E. bangladeshi* cannot be differentiated from *E. histolytica* with no ingested red blood cells or *E. dispar*.

[b] Although some individuals have changed the species designation for the genus *Giardia* to *G. duodenalis* or *G. intestinalis*, there is no general agreement. Therefore, for this listing, the name *Giardia lamblia* is retained.

[c] The designation *Microsporidium* is not a true genus, but a “catch-all” for organisms that have not been (or may never be) identified to the genus and/or species levels (*Microsporidium ceylonensis*, *Microsporidium africanum*). However, it is now listed as one of the genera of microsporidia infecting humans.

TABLE A1.7 Cosmopolitan distribution of common parasitic infections (North America, Mexico, Central America, South America, Europe, Africa, Asia, and Oceania)

Category	Species
Protozoa	
Intestinal	*Blastocystis* spp.
	Cryptosporidium spp.
	Cyclospora cayetanensis
	Dientamoeba fragilis
	Entamoeba histolytica
	Entamoeba dispar[a]
	Giardia lamblia
	Cystoisospora belli
	Microsporidia[b]
Tissue	*Toxoplasma gondii*
	Microsporidia[b]
Other	*Balamuthia mandrillaris*
	Microsporidia[b]
	Naegleria and *Acanthamoeba* spp.
	Trichomonas vaginalis
Cestodes	*Hymenolepis nana*
	Taenia saginata
Nematodes	
Intestinal	*Ascaris lumbricoides*
	Enterobius vermicularis
	Hookworm
	Strongyloides stercoralis
	Trichuris trichiura
Tissue	*Trichinella* spp.

[a] The name *Entamoeba histolytica* is used to designate the true pathogen, while the name *E. dispar* is now being used to designate the nonpathogen. However, unless trophozoites containing ingested red blood cells (*E. histolytica*) are seen, the two organisms cannot be differentiated on the basis of morphology.

[b] Microsporidia have now been reclassified with the fungi.

TABLE A1.8 Body sites and specimen collection[a]

Site	Specimen options	Collection method[b]
Blood	Smears of whole blood	Thick and thin films, fresh or with anticoagulant
	Anticoagulated blood	Anticoagulant EDTA (1st choice) Heparin (2nd choice)
Bone marrow	Aspirate	Sterile
Central nervous system	Spinal fluid	Sterile
	Brain biopsy specimen	Sterile
Cutaneous ulcers	Aspirates from below surface	Sterile plus air-dried smears
	Biopsy specimen	Sterile, nonsterile to histopathology (formalin acceptable)
Eyes	Biopsy specimen	Sterile (in saline), nonsterile to histopathology
	Scrapings	Sterile (in saline)
	Contact lens	Sterile (in saline)
	Lens solution	Sterile (unopened commercial solutions not acceptable)
Intestinal tract	Fresh stool	0.5-pt (ca. 0.237-liter) waxed container
	Preserved stool[c]	5 or 10% formalin, MIF, SAF, Schaudinn's fluid (mercury, copper, or zinc base)(with PVA), single-vial systems/Universal Fixative (no mercury, no formalin, no PVA)
	Sigmoidoscopy material	Fresh, PVA, or Schaudinn's smears
	Duodenal contents	Entero-Test or aspirates
	Anal impression smear	Cellulose tape (pinworm examination) or other collection device
	Adult worm or worm segments	Saline, 70% alcohol
Liver, spleen	Aspirates	Sterile, collected in 4 separate aliquots (liver)
	Biopsy specimen	Sterile, nonsterile to histopathology
Lungs	Sputum	True sputum (not saliva)
	Induced sputum	Sterile, air-dried smears
	Bronchoalveolar lavage fluid	Sterile, air-dried smears
	Transbronchial aspirate	Sterile, air-dried smears
	Tracheobronchial aspirate	Sterile, air-dried smears
	Brush biopsy specimen	Sterile, air-dried smears
	Open-lung biopsy specimen	Sterile
	Aspirate	Sterile, air-dried smears
Muscle	Biopsy specimen	Fresh, squash preparation, nonsterile to histopathology (formalin acceptable)
Skin	Scrapings	Aseptic, smear or vial
	Skin snip	No preservative
	Biopsy specimen	Sterile (in saline), nonsterile to histopathology
Urogenital system	Vaginal discharge	Saline swab, transport swab (no charcoal), culture medium, plastic-envelope culture; air-dried smear for FA
	Urethral discharge	Same as above
	Prostatic secretions	Same as above
	Urine	Single unpreserved specimen (early morning), 24-h unpreserved specimen

[a] Modified from Garcia LS, ed, *Clinical Microbiology Procedures Handbook*, 3rd ed, ASM Press, Washington, DC, 2010.

[b] FA, fluorescent antibody; MIF, merthiolate-iodine-formalin; PVA, polyvinyl alcohol; SAF, sodium acetate-acetic acid-formalin.

[c] A number of new stool fixatives are now available; some use a zinc sulfate base rather than mercuric chloride. Some collection vials can be used as a single-vial system; both the concentration and permanent stained smear can be performed from the preserved stool. However, not all single-vial systems provide material that can be used for fecal immunoassay procedures. The Universal Fixative is now available and can be used for the ova and parasite examination, most fecal immunoassays, and some PCR (fixative has no formalin, no mercury, and no PVA).

TABLE A1.9 Body sites and possible parasites recovered (trophozoites, cysts, oocysts, spores, adults, larvae, eggs, amastigotes, and trypomastigotes)[a]

Site	Parasites
Blood	
Red cells	*Plasmodium* spp.
	Babesia spp.
Leukocytes	*Leishmania* spp.
	Toxoplasma gondii
Whole blood or plasma	*Trypanosoma* spp.
	Microfilariae
Bone marrow	*Leishmania* spp.
	Trypanosoma cruzi
	Plasmodium spp.
Central nervous system	*Taenia solium* (cysticerci)
	Echinococcus spp.
	Naegleria fowleri
	Acanthamoeba and *Hartmanella* spp.
	Balamuthia mandrillaris
	Sappinia diploidea
	Toxoplasma gondii
	Microsporidia[b]
	Trypanosoma spp.
Cutaneous ulcers	*Leishmania* spp.
	Acanthamoeba spp.
	Entamoeba histolytica
Eyes	*Acanthamoeba* spp.
	Toxoplasma gondii
	Loa loa
	Microsporidia[b]
	Dirofilaria spp.
	Thelazia spp.
Intestinal tract	*Entamoeba histolytica*
	Entamoeba dispar, *Entamoeba moshkovskii*, *Entamoeba bangladeshi*
	Entamoeba coli
	Entamoeba hartmanni
	Endolimax nana
	Iodamoeba bütschlii
	Blastocystis spp.
	Giardia lamblia
	Chilomastix mesnili
	Dientamoeba fragilis
	Pentatrichomonas hominis
	Balantidium coli
	Cryptosporidium spp.
	Cyclospora cayetanensis
	Cystoisospora belli
	Encephalitozoon spp.
	Enterocytozoon bieneusi
Intestinal tract *(cont.)*	Microsporidia[b]
	Ascaris lumbricoides
	Enterobius vermicularis
	Hookworm
	Strongyloides stercoralis
	Trichuris trichiura
	Hymenolepis nana
	Hymenolepis diminuta
	Taenia saginata
	Taenia solium
	Diphyllobothrium latum
	Clonorchis (*Opisthorchis*) *sinensis*
	Paragonimus spp.
	Schistosoma spp.
	Fasciolopsis buski
	Fasciola hepatica
	Metagonimus yokogawai
	Heterophyes heterophyes
Liver and spleen	*Echinococcus* spp.
	Entamoeba histolytica
	Leishmania spp.
	Microsporidia[b]
	Capillaria hepatica
	Clonorchis (*Opisthorchis*) *sinensis*
Lungs	*Pneumocystis jiroveci*[b]
	Cryptosporidium spp.[c]
	Echinococcus spp.
	Paragonimus spp.
	Toxoplasma gondii
	Helminth larvae
Muscles	*Taenia solium* (cysticerci)
	Trichinella spp.
	Onchocerca volvulus (nodules)
	Trypanosoma cruzi
	Microsporidia[b]
Skin	*Entamoeba histolytica*
	Acanthamoeba spp.
	Balamuthia mandrillaris
	Leishmania spp.
	Onchocerca volvulus
	Microfilariae
Urogenital system	*Trichomonas vaginalis*
	Schistosoma spp.
	Microsporidia[b]
	Microfilariae

---

[a] Modified from Garcia LS, ed, *Clinical Microbiology Procedures Handbook*, 3rd ed, ASM Press, Washington, DC, 2010. This table does not include every possible parasite that could be found in a particular body site. However, the most likely organisms have been listed.

[b] Now classified with the fungi.

[c] Disseminated in severely immunosuppressed individuals.

TABLE A1.10 Body site, specimen and procedures, recommended methods, relevant parasites, and comments[a]

Body site	Procedures and specimens	Recommended methods and relevant parasites[b]	Comments
Amniotic fluid	PCR (and/or culture): fresh material	PCR based on the detection of highly repetitive gene sequences is the method of choice.	Only applicable to confirm suspected prenatal *Toxoplasma* infections.
	Animal inoculation (toxoplasmosis)		
Blood	Microscopy[b]: thin and thick blood films; fresh blood or EDTA blood (fill EDTA tube completely with blood, then mix)	Giemsa or other blood stains (all blood parasites); hematoxylin-based stain (sheathed microfilariae); for malaria, thick and thin blood films are mandatory and should be prepared within 30–60 min of blood collection via venipuncture (other tests may be used as well); Wright-Giemsa stain or Diff-Quik (rapid stains) can also be used.	Most drawings and descriptions of blood parasites are based on Giemsa-stained blood films. Although Wright's stain (or Wright-Giemsa combination stain) will work, stippling in malaria may not be visible and the organisms' colors will not match the descriptions. However, with other stains (those listed above, in addition to some of the "rapid" blood stains), the organisms are detectable on the blood films. The use of blood collected with anticoagulant (rather than fresh) has direct relevance to the morphology of malaria organisms seen in peripheral blood films. If the blood smears are prepared after more than 1 h, stippling may not be visible, even if the correct pH buffers are used. Also, if blood is kept at room temperature (with the stopper removed), the male microgametocyte may exflagellate and fertilize the female macrogametocyte, and development continues within the tube of blood as it would in the mosquito host. The ookinete may actually resemble a *Plasmodium falciparum* gametocyte. The microgamete may resemble spirochetes: white blood cells serve as the internal quality control for every blood film; if the leukocytes exhibit acceptable morphology, parasites present will also be acceptable per staining and morphology characteristics.
	Concentration methods: EDTA blood	Buffy coat, fresh blood films for detection of moving microfilariae or trypanosomes; QBC, a screening method for blood parasites (hematocrit tube contains acridine orange), has been used for malaria, *Babesia*, trypanosomes, and microfilariae; it is usually impossible to identify malaria organisms to the species level; this requires high levels of training; confirmation to species often requires examination of thin blood films.	
	Antigen detection: EDTA-blood for malaria, serum or plasma for circulating antigens (hemolyzed blood can interact in some tests)	Commercial test kits for malaria and some microfilariae	
	PCR: EDTA-blood, ethanol-fixed or unfixed thin and thick blood films, coagulated blood, possible with hemolyzed or frozen blood samples	Sensitivity not higher than thick films for *Plasmodium* spp.; much more sensitive for *Leishmania* (peripheral blood is used from immunodeficient patients only). Sequencing of PCR product is often used for species or genotype identification.	So far no commercial tests are available; some reference laboratories offer PCR or other molecular procedures for all five species of human malaria, *Babesia*, *Leishmania*, and trypanosomes. High laboratory standards required (may work with frozen, coagulated, or hemolyzed blood samples).
	Specific antibody detection: serum or plasma, anticoagulated or coagulated blood (hemolyzed blood can cause problems in some tests)	Most commonly used are EIA (many test kits commercially available), EITB (commercially available for some parasites), and IFA.	Many laboratories are using in-house tests; only a few fully defined antigens are available; sensitivities and specificities of the tests should be validated by the laboratory.
Bone marrow	Biopsy specimens or aspirates Microscopy: thin and thick films with aspirate collected in EDTA	Giemsa or other blood stains (including rapid stains) (all blood parasites)	*Leishmania* amastigotes are recovered in cells of the reticuloendothelial system; if films are not prepared directly after sample collection, infected cells may disintegrate. Sensitivity of microscopy is low, so it should be used only in combination with other methods.

	Cultures: sterile material in EDTA or culture medium	Culture for *Leishmania* (or *Trypanosoma cruzi*)	Positive control cultures should be performed with patient cultures.
	PCR: aspirate in EDTA	PCR for blood parasites including *Leishmania* and *Toxoplasma* and rare other parasites	
Central nervous system	Microscopy: spinal fluid and CSF (wet examination, stained smears), brain biopsy specimen (touch or squash preparations, stained)	Stains: Giemsa or other blood stains (trypanosomes, *Toxoplasma*); Giemsa, trichrome, or calcofluor (amebae [*Naegleria* or *Sappinia*—PAM; *Acanthamoeba* or *Balamuthia*—GAE]); Giemsa, acid-fast, PAS, modified trichrome, silver methenamine (microsporidia) (tissue Gram stains also recommended for microsporidia in routine histologic preparations); H&E, routine histology (larval cestodes, *Taenia solium* cysticerci, *Echinococcus* spp.)	If CSF is received (with no suspect organism suggested), Giemsa would be the best choice; however, modified trichrome or calcofluor is also recommended as a second stain (amebic cysts, microsporidia). If brain biopsy material is received (particularly from an immunocompromised patient), cultivation is recommended for microsporidial isolation and PCR for identification to the species or genotype level. A small amount of the sample should always be stored frozen for PCR analyses in case the results of the other methods are inconclusive.
	Culture: sterile aspirate or biopsy material (in physiologic NaCl)	Free-living amebae (exception: *Balamuthia* does not grow in the routine agar/bacterial overlay method), microsporidia, and *Toxoplasma* (can be cultured in tissue culture media)	
	PCR: aspirate or biopsy material fresh, frozen, or fixed in ethanol	Protozoa and helminths, species and genotype characterization	
Cutaneous ulcers	Microscopy: aspirate, biopsy (smears, touch or squash preparations, histologic sections) Cultures (less common) PCR: aspirate, biopsy material fresh, frozen, or fixed in ethanol	Giemsa or other blood stains (*Leishmania*); H&E, routine histology (*Acanthamoeba* spp., *Entamoeba histolytica*) *Leishmania* (often bacterial contamination, culture problems), free-living amebae, *Leishmania* (species identification)	The most likely causative parasites would be *Leishmania*, which would stain with Giemsa. PAS could be used to differentiate *Histoplasma capsulatum* from *Leishmania* in tissue. In immunocompromised patients, skin ulcers have been documented with *Acanthamoeba* or *Entamoeba histolytica* amebae as causative agents; cultures of material from cutaneous ulcers may be contaminated with bacteria; PCR would be the method of choice.
Eyes	Microscopy: smears, touch or squash preparations; biopsy specimens, scrapings, contact lens, sediment of lens solution	Calcofluor for cyst only (amebae [*Acanthamoeba*]); Giemsa for trophozoites and cysts (amebae); modified trichrome (preferred) or silver methenamine stain, PAS, acid-fast (microsporidial spores), H&E, routine histology (cysticerci, *Loa loa*, *Toxoplasma*)	Some free-living amebae (most commonly *Acanthamoeba*) have been implicated as a cause of keratitis. Although calcofluor stains the cyst walls, it does not stain the trophozoites. Therefore, in suspect cases of amebic keratitis, both stains should be used. H&E (routine histology) can be used to detect and confirm cysticercosis. The adult worm of *Loa loa*, when removed from the eye, can be stained with a hematoxylin-based stain (Delafield's) or can be stained and examined by routine histology. Microsporidia: confirmation to the species or genotype levels can be done by PCR and sequence analyses or EM; however, the spores could be found by routine light microscopy with modified trichrome, calcofluor, and/or tissue Gram stains.
	Culture: fresh material (see above) in PBS supplemented with antibiotics if possible to avoid bacterial growth	Cultures: free-living amebae, *Toxoplasma*, microsporidia	
	PCR: fresh material in physiologic NaCl or PBS, ethanol or frozen	Free-living amebae, *Toxoplasma*, microsporidian species and genotype identification	

(continued)

TABLE A1.10 Body site, specimen and procedures, recommended methods, relevant parasites, and comments[a] *(continued)*

Body site	Procedures and specimens	Recommended methods and relevant parasites[b]	Comments
Intestine	Stool and other intestinal material		Stool fixation with formalin or formalin-containing fixatives preserves parasite morphology (trophozoites marginal), allows prolonged storage (room temperature) and long transportation, and prevents hatching of *Schistosoma* eggs, but makes *Strongyloides* larval concentration difficult and impedes further PCR analyses. Single-vial Universal Fixative is now available (no mercury, no formalin, no PVA); can be used for O&P, most fecal immunoassays, special stains, some PCR
	Microscopy: stool, sigmoidoscopy material, duodenal contents (all fresh or preserved), direct wet smear, concentration methods	Concentration methods: ethyl acetate sedimentation of SAF-fixed stool samples (most protozoa); flotation or combined sedimentation flotation methods (helminth ova); agar or Baermann concentration (larvae of *Strongyloides* spp., fresh stool required)	Agar plate for *Strongyloides* is more sensitive than routine O&P.
		Direct wet smear (direct examination of unpreserved fresh material is also used (motile protozoan trophozoites; helminth eggs, protozoan cysts may also be detected).	Taeniid eggs cannot be identified to the species level.
		Stains: trichrome or iron hematoxylin (intestinal protozoa); modified trichrome (microsporidia); modified acid-fast (*Cryptosporidium*, *Cyclospora*, *Cystoisospora*)	Microsporidia: confirmation to the species or genotype levels requires PCR or EM; however, modified trichrome and/or calcofluor stains can be used to confirm the presence of spores.
	Anal impression smear	Adhesive cellulose tape, no stain (*Enterobius vermicularis*)	Four to six consecutive negative tapes are required to rule out infection with pinworm (*Enterobius vermicularis*).
	Adult worms or tapeworm segments (proglottids)	Carmine stains (rarely used for adult worms or cestode segments). Proglottids can usually be identified to the genus level (*Taenia*, *Diphyllobothrium*, *Hymenolepis*) without using tissue stains.	Worm segments can be stained with special stains. However, after dehydration through alcohols and xylenes (or xylene substitutes) without prior staining, the sexual organs and the branched uterine structure will be visible, allowing identification of the proglottid to the species level, providing the proglottids are gravid.
	Antigen detection (fresh or frozen material, suitability of fixation is test dependent)	Commercial immunoassays, e.g., EIA, FA, cartridge formats (*Entamoeba histolytica*, the *Entamoeba histolytica/E. dispar* group, *Giardia lamblia*, *Cryptosporidium* spp.); in-house tests for *T. solium* and *T. saginata* and other parasites	Coproantigens can be detected in the prepatent period and independently from egg excretion.
	PCR: fresh, frozen, or ethanol-fixed material	Few commercial tests available; primers for genus or species identification of most helminths and protozoa are published; commercial instrumentation available, *Entamoeba histolytica*, *Giardia lamblia*, *Cryptosporidium*, *Cyclospora cayetanensis*	Due to potential inhibition after DNA extraction from stool samples, concentration or isolation methods may be required prior to DNA extraction. However, new DNA isolation kits facilitate isolation of high-quality DNA from stool. Sequence analyses may be required for species or genotype identification.

	Biopsy specimens		
	Microscopy: fixed for histology or touch or squash preparations for staining	H&E, routine histology (*Entamoeba histolytica*, *Cryptosporidium*, *Cyclospora*, *Cystoisospora belli*, *Giardia*, microsporidia); less common findings would include *Schistosoma* spp., hookworm, or *Trichuris*	Special stains may be helpful for the identification of microsporidia: tissue Gram stains, silver stains, PAS, and Giemsa or modified acid-fast stains for the coccidia
Liver and spleen	Biopsy specimens or aspirates Microscopy: unfixed material in physiologic NaCl; fixed for histology	Examination of wet smears for *Entamoeba histolytica* (trophozoites), protoscolices of *Echinococcus* spp. or eggs of *Capillaria hepatica*; Giemsa (*Leishmania*, other protozoa and microsporidia); H&E (routine histology)	There are definite risks associated with punctures (aspirates and/or biopsy) of spleen or liver lesions (*Echinococcus*). Always keep a small amount of material frozen for PCR.
	Culture: sterile preparation of fresh material	For *Leishmania* (not common)	
	Animal inoculation: sterile preparation of fresh material	Intraperitoneal inoculation of *E. multilocularis* cyst material for viability test after long-term chemotherapy	
	PCR: fresh, frozen, or ethanol fixed	Species or genotype identification (e.g., *Echinococcus* spp.)	
Respiratory tract	Sputum, induced sputum, nasal and sinus discharge, bronchoalveolar lavage fluid, transbronchial aspirate, tracheobronchial aspirate, brush biopsy specimen, open-lung biopsy specimen Microscopy: unfixed material, treated for smear preparation	Helminth larvae (*Ascaris*, *Strongyloides*), eggs (*Paragonimus*, *Capillaria*), or hooklets (*Echinococcus*) can be recovered in unstained respiratory specimens; stains include Giemsa for many protozoa including *Toxoplasma* tachyzoites, modified acid-fast stains (*Cryptosporidium*), and modified trichrome (microsporidia); routine histology with H&E; silver methenamine stain, PAS, acid-fast, and tissue Gram stains for helminths, protozoa, and microsporidia	Immunoassay reagents (FA) are available for the diagnosis of pulmonary cryptosporidiosis (may require validation). Routine histologic procedures allow the identification of any of the helminths or helminth eggs present in the lungs. Disseminated toxoplasmosis and microsporidiosis are well documented, with organisms being found in many different respiratory specimens.
	PCR: fresh, frozen, or fixed in ethanol		
Muscles	Biopsy material Microscopy: unfixed, touch and squash preparations or fixed for histology and EM	Larvae of *Trichinella* spp. can be identified unstained (species identification with single larvae by PCR); H&E, routine histology (*Trichinella* spp., cysticerci); silver methenamine stain, PAS, acid-fast, tissue Gram stains, EM (several genera of microsporidia)	If *Trypanosoma cruzi* is present in the striated muscle, the organisms could be identified in routine histology preparations. Modified trichrome, tissue Gram stains, and/or calcofluor stains can be used to confirm the presence of microsporidial spores.
	PCR: fresh, frozen, or ethanol fixed	Microsporidian identification to the species level requires subsequent sequencing.	
Skin	Aspirates, skin snips, scrapings, biopsy specimens	See cutaneous ulcer (above).	Any of the potential parasites present can be identified by routine histology procedures.

(continued)

TABLE A1.10 Body site, specimen and procedures, recommended methods, relevant parasites, and comments[a] *(continued)*

Body site	Procedures and specimens	Recommended methods and relevant parasites[b]	Comments
	Microscopy: wet examination, stained smear (or fixed for histology or EM)	Wet preparations (microfilariae), Giemsa-stained smears or H&E, routine histology (*Onchocerca volvulus*, *Dipetalonema streptocerca*, *Dirofilaria repens*, other larvae causing cutaneous larva migrans [zoonotic *Strongyloides* spp.], hookworms), *Leishmania*, *Acanthamoeba* spp., *Balamuthia mandrillaris*, *Entamoeba histolytica*, microsporidia, and arthropods (*Sarcoptes* and other mites)	
	PCR: fresh, frozen, or fixed in ethanol	Primers for most relevant parasite species available	
Urogenital system	Vaginal discharge, saline swab, transport swab (no charcoal), air-dried smear for FA, urethral discharge, prostatic secretions, urine (single unpreserved, 24-h unpreserved, or early-morning specimens)	Giemsa, immunoassay reagents (FA) (*Trichomonas vaginalis*); Delafield's hematoxylin (microfilariae); modified trichrome (microsporidia); H&E, routine histology PAS, acid-fast, tissue Gram stains (microsporidia); direct examination of urine sediment for *Schistosoma haematobium* eggs or microfilariae	Although *T. vaginalis* is probably the most common parasite identified, there are others to consider, the most recently implicated organisms being in the microsporidian group. Microfilariae could also be recovered and stained. Fixation of urine with formalin prevents hatching of *Schistosoma* eggs. Perform concentration using saline to prevent premature hatching of schistosome eggs. Material must be put into culture medium immediately after collection; do not cool or freeze (*T. vaginalis*).
	Microscopy: wet smears, smears of urine sediment, stained smears	Identification and propagation of *T. vaginalis* (commercialized plastic-envelope culture systems available); moving trophozoites can be detected using microscopy (or in Giemsa-stained smears)	
	Cultivation: vaginal or urethral discharge or swab preparations		
	Antigen detection (vaginal swab)	Commercial immunoassay (rapid formal), *T. vaginalis*	
	Probe	Commercial instrumentation, *T. vaginalis*	
	PCR: fresh, frozen, or fixed in ethanol		

---

[a] CSF, cerebrospinal fluid; EIA, enzyme immunoassay; EITB, enzyme-linked immunoelectrotransfer blot (Western blot); EM, electron microscopy; FA, fluorescent antibody; GAE, granulomatous amebic encephalitis; GI, gastrointestinal; H&E, hematoxylin and eosin; IFA, indirect fluorescent-antibody assay; O&P, ova and parasite exam; PAM, primary amebic meningoencephalitis; PAS, periodic acid-Schiff stain; PBS, phosphate-buffered saline; QBC, quantitative buffy coat; SAF, sodium acetate-acetic acid-formalin.

[b] Many parasites or parasite stages may be detected in standard histologic sections of tissue material. However, species identification is difficult and additional examinations may be required. Usually, these techniques are not considered first-line methods. Additional methods like EM (electron microscopy) are carried out only by specialized laboratories and are not available for standard diagnostic purposes. EM examination for species identification has largely been replaced by PCR assays.

TABLE A1.11 Examination of tissue and body fluids[a]

Suspected causative agent	Disease(s)	Appropriate test(s)[b]	Positive result
Protozoa			
Naegleria fowleri	Primary amebic meningoencephalitis (PAM)	1. Wet examination of CSF (not in counting chamber) 2. Stained preparation of CSF sediment	Trophozoites present and identified
Acanthamoeba spp.	Amebic keratitis, chronic meningoencephalitis (granulomatous amebic encephalitis [GAE]); skin lesions	1. Culture or stained smears 2. Calcofluor (cysts only) 3. Biopsy for routine histology	Trophozoites and/or cysts present and identified
Balamuthia mandrillaris	Chronic meningoencephalitis (GAE)	1. Calcofluor (cysts only) 2. Biopsy for routine histology	Trophozoites and/or cysts present and identified
Entamoeba histolytica	Amebiasis; cutaneous, intestinal, extraintestinal	1. Biopsy for routine histology 2. Immunoassays	Trophozoites present and identified
Giardia lamblia	Giardiasis, intestinal	1. Duodenal aspirate 2. Duodenal biopsy or routine histology 3. Entero-Test capsule 4. Immunoassays	Trophozoites and/or cysts present and identified
Leishmania spp.			
Cutaneous lesions	Cutaneous leishmaniasis	1. Material from under bed of ulcer A. Smear B. Culture C. Animal inoculation 2. Punch biopsy A. Routine histology B. Squash preparation C. Culture D. Animal inoculation	Amastigotes recovered in macrophages of skin or from animal inoculation; other stages recovered in culture
Mucocutaneous lesions	Mucocutaneous leishmaniasis	As for cutaneous leishmaniasis	Amastigotes recovered in macrophages of skin and mucous membranes or from inoculation of animals; other stages recovered in culture
Visceral	Visceral leishmaniasis (kala azar)	1. Buffy coat A. Stain B. Culture C. Animal inoculation 2. Bone marrow A. Stain B. Culture C. Animal inoculation 3. Liver or spleen biopsy A. Routine histology B. Stain C. Culture D. Animal inoculation	Amastigotes recovered in cells of reticuloendothelial system; other stages recovered in culture

(continued)

TABLE A1.11 Examination of tissue and body fluids[a] *(continued)*

Suspected causative agent	Disease(s)	Appropriate test(s)[b]	Positive result
Toxoplasma gondii	Toxoplasmosis	1. Lymph node biopsy A. Routine histology B. Tissue culture isolation C. Animal inoculation 2. Serology	Identification of organisms plus appropriate serologic test results
Cryptosporidium spp.	Cryptosporidiosis	1. Duodenal scraping 2. Duodenal biopsy A. Stain B. Routine histology 3. Other tissue biopsy A. Routine histology B. Squash preparation 4. Sputum (modified AFB stains) 5. Immunoassays	Identification of organisms in microvillus border or in other tissues (lung and gallbladder have also been involved)
Microsporidia[c] *Nosema* spp. *Encephalitozoon* spp. *Enterocytozoon* spp. *Pleistophora* spp. *Trachipleistophora* spp. *Anncaliia* spp. *Microsporidium* spp. *Vittaforma corneae* *Tubulinosema* sp.	Microsporidiosis (now classified with the fungi)	Routine histology (fair); acid-fast, PAS, modified trichrome, Giemsa, and tissue Gram stains recommended (spores); animal inoculation not recommended (latent infections); EM or PCR may be necessary to confirm genus	These organisms (spores) have been found as insect or other animal parasites; the most common route of infection is probably ingestion. Human cases involve gastrointestinal tract, muscle, and CSF (AIDS); other body sites have also been documented; not limited to compromised patients
Helminths			
Larvae (*Ascaris lumbricoides*, *Strongyloides stercoralis*)	"Pneumonia"	Sputum, wet preparation	This is an incidental finding but has been reported in severe infections
Eggs (*Paragonimus* spp.)	Paragonimiasis	Sputum, wet preparation Stool, routine O&P	Eggs will be coughed up and will appear as "iron filings"; eggs can also be found in stool
Hooklets (*Echinococcus* spp.)	Hydatid disease	Sputum, wet preparation	Rare finding, but hooklets can be found when the hydatid cyst is in the lungs
Onchocerca volvulus, *Mansonella streptocerca*	Onchocerciasis	Skin	Skin snips examined in saline; microfilariae may be present
Schistosoma spp.	Schistosomiasis	1. Rectal valve biopsy 2. Bladder biopsy	Eggs present and identified

[a] Modified from Garcia LS, ed, *Clinical Microbiology Procedures Handbook*, 3rd ed, ASM Press, Washington, DC, 2010. AFB, acid-fast bacillus; CSF, cerebrospinal fluid; EM, electron microscopy; O&P, ova and parasite exam; PAS, periodic acid-Schiff.

[b] PCR is now being used for the identification of a number of human parasites; however, these tests are generally limited to academic or reference centers. Routine laboratory use is not common.

[c] Now classified with the fungi.

TABLE A1.12 Key characteristics of protozoa of the intestinal tract and urogenital system[a]

Organism	Trophozoite or tissue stage	Cyst or other stage in specimen	Comments
Amebae			
Entamoeba histolytica (pathogenic)	Cytoplasm is clean; presence of RBCs is diagnostic, but cytoplasm may also contain some ingested bacteria; peripheral nuclear chromatin is evenly distributed with central, compact karyosome.	Mature cyst contains 4 nuclei; chromatoidal bars have smooth, rounded ends; cannot be differentiated from *E. dispar*	Considered pathogenic; should be reported to Public Health; trophozoites can be confused with macrophages and cysts can be confused with PMNs in the stool.
Entamoeba dispar (nonpathogenic)	Morphology identical to that of *E. histolytica* (confirmed by presence of RBCs in cytoplasm). If no RBCs present, molecular testing or fecal immunoassays are necessary to confirm species designation.	Mature cyst has morphology identical to that of *E. histolytica*.	Nonpathogenic; morphology resembles *E. histolytica*; these organisms should be reported as *Entamoeba histolytica/E. dispar* and reported to Public Health; immunoassay reagents are now available to identify the *E. histolytica/E. dispar* group and to differentiate pathogenic *E. histolytica* and nonpathogenic *E. dispar*; some laboratories may decide to use these reagents on a routine basis, depending on positivity rate and cost.
Entamoeba histolytica/E. dispar (some like to add the word "group" to indicate the two organisms cannot be differentiated on the basis of morphology unless RBCs are seen within the cytoplasm or *E. histolytica* is confirmed using species-specific immunoassays.			Correct way to report, unless species-specific immunoassay is used to identify *E. histolytica* or trophozoites are seen with ingested RBCs (*E. histolytica*). *E. moshkovskii* and *E. bangladeshi* look very similar to the *E. histolytica/E. dispar* group. Some have recommended using the term "*Entamoeba* complex."
Entamoeba hartmanni (nonpathogenic)	Looks identical to *E. histolytica/E. dispar* but is smaller (<12 µm); RBCs are not ingested.	Mature cyst contains 4 nuclei but often has only 2; chromatoidal bars are often present and look like those of *E. histolytica/E. dispar* (size, <10 µm).	Shrinkage occurs on the permanent stain due to dehydration steps (especially in the cyst form). *E. histolytica/E. dispar* may actually be below the 12- and 10-µm cutoff limits and can be as much as 1.5 µm below the limits quoted for wet preparation measurements.
Entamoeba coli (nonpathogenic)	Cytoplasm is dirty and may contain ingested bacteria or debris; peripheral nuclear chromatin is unevenly distributed, with a large, eccentric karyosome.	Mature cyst contains 8 nuclei; more may be seen; chromatoidal bars (if present) tend to have sharp, pointed ends.	If a smear is too thick or thin and if stain is too dark or light, *E. histolytica/E. dispar* and *E. coli* can often be confused, since there is much overlap in morphology.
Endolimax nana (nonpathogenic)	Cytoplasm is clean, not diagnostic, with a great deal of nuclear variation; there may even be some peripheral nuclear chromatin. Normally only karyosomes are visible.	Cyst is round to oval, with the 4 nuclear karyosomes being visible.	There is more nuclear variation in this ameba than any others. The organisms can be confused with *Dientamoeba fragilis* and/or *E. hartmanni*.

(continued)

TABLE A1.12 Key characteristics of protozoa of the intestinal tract and urogenital system[a] *(continued)*

Organism	Trophozoite or tissue stage	Cyst or other stage in specimen	Comments
Iodamoeba bütschlii (nonpathogenic)	Cytoplasm contains much debris; organisms are usually larger than *E. nana* but may look similar; large karyosome.	Cyst contains single nucleus (may be "basket nucleus") with bits of nuclear chromatin arranged on the nuclear membrane (the karyosome is the basket, bits of chromatin are the handle); large glycogen vacuole	Glycogen vacuole stains brown with the addition of iodine in the wet preparation; "basket nucleus" is more common in cyst but can be seen in trophozoite; vacuole may be so large that the cyst collapses on itself.
Blastocystis spp. (pathogenic) undergoing review for possible reclassification; multiple strains or species that look the same (~half are pathogenic, half are nonpathogenic)	Trophozoites may/may not be seen; often in patients with diarrhea; difficult to identify	Central body forms most common; tremendous size variation; central area may or may not stain; outer perimeter contains multiple nuclei (often seen as various sized dots)	These are the most common GI tract protozoa worldwide, much more common than *Giardia* or *Dientamoeba* (tend to be equal or *Dientamoeba* more common than *Giardia* in many areas); symptomatic patients tend to be treated.
Flagellates			
Giardia lamblia (pathogenic)	Trophozoites are teardrop shaped from the front and like a curved spoon from the side; contain nuclei, linear axonemes, and curved median bodies.	Cysts are round to oval, containing multiple nuclei, axonemes, and median bodies.	Organisms live in the duodenum, and multiple stool specimens may be negative; additional sampling techniques (aspiration, Entero-Test) may be needed; fecal immunoassays are helpful.
Chilomastix mesnili (nonpathogenic)	Trophozoites are teardrop shaped; cytostome must be visible for identification.	Cyst is lemon shaped with 1 nucleus and a curved fibril called the shepherd's crook.	The cyst can be identified much more easily than the trophozoite form. The trophozoite looks like some of the other small flagellates.
Dientamoeba fragilis (pathogenic)	Cytoplasm contains debris; may contain 1 or 2 nuclei (chromatin often fragmented into 4 dots).	Cyst form has now been identified; appears to have double wall; percentage is quite low (~1–2%); thus it can be very difficult to find and identify.	Tremendous size and shape range on a single smear; trophozoites with 1 nucleus can resemble *E. nana*.
Trichomonas vaginalis (pathogenic)	Supporting rod (axostyle) is present; undulating membrane comes halfway down the organism; small dots may be seen in the cytoplasm along the axostyle.	No known cyst form	Recovered from genitourinary system; often diagnosed at bedside with wet preparation (motility)
Pentatrichomonas hominis (nonpathogenic)	Supporting rod (axostyle) is present; undulating membrane comes all the way down the organism; small dots may be seen in the cytoplasm along the axostyle.	No known cyst form	Recovered in stool; trophozoites may resemble other small flagellate trophozoites.
Ciliates			
Balantidium coli (pathogenic)	Very large trophozoites (50–100 μm long) covered with cilia; large bean-shaped macronucleus present; very small micronucleus is difficult to see.	Morphology not significant with exception of large, bean-shaped macronucleus; small micronucleus is difficult to see.	Rarely seen in the United States; causes severe diarrhea with large fluid loss; will be seen in proficiency-testing specimens or possibly people who work around pigs

Coccidia			
Cryptosporidium spp. (pathogenic)	Seen in intestinal mucosa (edge of brush border), gallbladder, and lungs; present in biopsy specimens	Oocysts seen in stool and/or sputum; organisms acid fast, measure 4–6 µm; hard to find if only a few are present	Chronic infection in the compromised host (internal autoinfective cycle), self-cure in the immunocompetent host; numbers of oocysts correlate with stool consistency; can cause severe, watery diarrhea; oocysts are immediately infective when passed.
Cyclospora cayetanensis (pathogenic)	Experience with this organism is not extensive; may be difficult to identify in tissue; since patients are immunocompetent, biopsy specimens will rarely be required or requested.	Oocysts seen in stool; approximately 8–10 µm in size; are unsporulated and thus difficult to recognize as coccidia; mimic *Cryptosporidium* on modified acid-fast-stained smears	Most infections are associated with the immunocompetent individual but may also be seen in the immunosuppressed patient; may be associated with traveler's diarrhea; oocysts are not immediately infective when passed. Within the United States, infections have been associated with contaminated food, including raspberries, basil, snow peas, and mesclun (baby lettuce leaves). PCR can detect 40 or fewer oocysts per 100 g of raspberries or basil but has a detection limit of around 1,000 per 100 g in mesclun lettuce.
Cystoisospora belli (pathogenic)	Seen in intestinal mucosal cells; seen in biopsy specimens; not as common as *Cryptosporidium*	Oocysts seen in stool; organisms are acid fast; best technique is concentration, not permanent stained smear	Thought to be the only *Cystoisospora* sp. that infects humans; oocysts are not immediately infective when passed.
Microsporidia[b] *Nosema* spp. *Encephalitozoon* spp. *Pleistophora* spp. *Trachipleistophora* spp. *Anncaliia* spp. *Enterocytozoon* spp. *Microsporidium* spp. *Vittaforma corneae* *Tubulinosema* sp.	Developing stages sometimes difficult to identify; spores can be identified by size, shape, and presence of polar tubules.	Depending on the genus involved, spores could be identified in stool or urine using the modified trichrome stain, calcofluor, or immunoassay reagents (available outside U.S.).	Spores are generally quite small (1–2.0 µm for *Enterocytozoon* spp.) and can easily be confused with other organisms or artifacts (particularly in stool). Infections tend to be present in immunosuppressed patients; however, they are not limited to this patient group.

---

[a] Modified from Garcia LS, ed, *Clinical Microbiology Procedures Handbook*, 3rd ed, ASM Press, Washington, DC, 2010. GI, gastrointestinal; PMN, polymorphonuclear neutrophils; RBC, red blood cells.

[b] Now classified with the fungi.

TABLE A1.13 Key characteristics of tissue protozoa[a]

Species	Shape and size	Other features[b]
Toxoplasma gondii		
Trophozoites (tachyzoites)	Crescent shaped; 4–6 µm long by 2–3 µm wide	Found in peritoneal fluid of experimentally infected mice; intracellular forms somewhat smaller and not usually seen in humans. May be isolated in tissue culture, particularly from CSF. Diagnosis is most frequently based on clinical history and serologic evidence (acute- and convalescent-phase sera).
Cysts (bradyzoites)	Generally spherical; 200 µm to 1 mm in diameter	Occur in many tissues (approximately 25% of the U.S. population have these organisms in the tissues, indicating past infection). Many infections are asymptomatic. Infections in the compromised host are very serious and involve the CNS. In these patients, particularly those with AIDS, diagnostic serologic titers may be very difficult to demonstrate and/or interpret. **Note** Organisms identified in histologic preparations or isolated in animals or tissue culture systems may or may not be the causative agent of the symptoms.
Cryptosporidium spp.	Oocyst usually round, 4–6 µm; each mature oocyst contains sporozoites (infective on passage)	Oocyst is usually the diagnostic stage in stool, sputum, and possibly other body specimens. Various other stages in the life cycle can be seen in biopsy specimens taken from the gastrointestinal tract (brush border of epithelial cells and intestinal tract) and other tissues (lung and gallbladder). A number of modified acid-fast stains have been used successfully. Detection methods using immunoassay reagents are also available. **Note** Infection in immunocompetent hosts is self-limiting; however, in immunodeficient patients (AIDS), the infection is chronic owing to an autoinfective capability in the life cycle. The number of oocysts usually correlates with the symptoms (watery diarrhea indicates many oocysts in the specimen). The more normal the stool, the more difficult it is to find the oocysts. Clinicians should be aware that risk groups include animal handlers, travelers, immunocompromised individuals, children in day care centers, and anyone who comes in contact with these individuals. Since the oocysts are immediately infective, nosocomial transmission has been documented.
Cyclospora cayetanensis	Oocyst usually round, 8–10 µm; each oocyst is immature on passage; no internal morphology visible; oocysts appear as "wrinkled cellophane"	The oocyst is the diagnostic stage in stool. Various other stages in the life cycle can be seen in biopsy specimens taken from the gastrointestinal tract (within epithelial cells and intestinal tract); oocysts are not immediately infectious when passed. The morphology is similar to that of *Cystoisospora belli*. A number of modified acid-fast stains have been used successfully to demonstrate the oocysts (quite acid-fast variable). Detection methods involving immunoassay reagents are under development.
Cystoisospora belli	Ellipsoidal oocyst; usual range, 20–30 µm long by 10–19 µm wide; sporocysts rarely seen broken out of oocysts but measure 9–11 µm	Mature oocyst contains 2 sporocysts with 4 sporozoites each; the usual diagnostic stage in feces is the immature oocyst, containing a spherical mass of protoplasm (diarrheic stool). Developing stages can be recovered from intestinal biopsy specimens. Oocysts are also acid fast and could be detected during acid-fast staining of stool for *Cryptosporidium*. Oocysts are often detected in the concentration sediment (wet preparation); they are not immediately infectious when passed.

(continued)

TABLE A1.13 *(continued)*

Species	Shape and size	Other features[b]
Microsporidia[c] *Nosema* spp. *Encephalitozoon* spp. *Enterocytozoon* spp. *Pleistophora* spp. *Trachipleistophora* spp. *Anncaliia* spp. *Microsporidium* spp. *Vittaforma corneae* *Tubulinosema* sp.	Spores are extremely small (1.5–2.5 μm) and have been recovered in all body organs, including the eye	These organisms have been found as insect or other animal parasites; the route of infection may be ingestion, inhalation, or direct inoculation (eyes). Histology results vary (spores are acid fast); PAS, silver, tissue Gram, and Giemsa stains are recommended for spores. Animal inoculation is not recommended; laboratory animals may carry occult infection. Electron microscopy or molecular methods may be necessary for confirmation and identification to the genus and species levels. Although difficult to diagnose, infections have been found in a large number of AIDS patients (*Enterocytozoon bieneusi*, *Encephalitozoon* [*Septata*] *intestinalis* in the intestinal tract, *Pleistophora* spp. in muscle, and various other microsporidia in other tissues). To date, it is still somewhat difficult to diagnose this infection by examining stool specimens prepared with optical brightening agents (calcofluor) or routine stains (modified trichrome stains). Diagnostic immunoassay reagents are under development.
Sarcocystis hominis, *S. suihominis*, *S. bovihominis*	Oocyst is thin walled and contains 2 mature sporocysts, each containing 4 sporozoites; the thin oocyst wall frequently ruptures; ovoidal sporocysts measure 9–16 μm long by 7.5–12 μm wide	Thin-walled oocyst or ovoidal sporocysts are found in stool. There have been reports of fever, severe diarrhea, abdominal pain, and weight loss in the compromised host, although the number of patients has been small. Infections occur from the ingestion of uncooked pork or beef. The life cycle occurs within the intestinal cells, with the eventual production of sporocysts in stool.
Sarcocystis "*lindemanni*" (this name is no longer used)	Shapes and sizes of skeletal and cardiac muscle sarcocysts vary considerably	When humans accidentally ingest oocysts from other animal stool sources, sarcocysts that develop in human muscle apparently do little if any harm. These could be identified by routine histologic methods. When humans are intermediate hosts, preventive measures involve careful disposal of animal feces that may contain the infective sporocysts. This may be impossible in the wilderness areas, where wild animals may serve as reservoir hosts for many of the different types of organisms that have been grouped under the term *Sarcocystis* "*lindemanni*." However, this name is no longer used.

[a] Modified from Garcia LS, ed, *Clinical Microbiology Procedures Handbook,* 3rd ed, ASM Press, Washington, DC, 2010.

[b] CNS, central nervous system; CSF, cerebrospinal fluid; PAS, periodic acid-Schiff.

[c] Now classified with the fungi.

TABLE A1.14 Key characteristics of helminths[a]

Helminths	Diagnostic stage[b]	Comments
Nematodes (roundworms)		
Ascaris lumbricoides (pathogenic)	Egg: both fertilized (oval to round with thick, mammilated/tuberculated shell) and unfertilized (tend to be more oval or elongate, with bumpy shell exaggerated) eggs can be found in stool; adult worms: 10–12 in. found in stool; rarely (in severe infections), migrating larvae can be found in sputum.	Unfertilized eggs do not float in flotation concentration method; adult worms tend to migrate when irritated (by anesthesia or high fever); hence, patients from areas of endemic infection should be checked for infection prior to elective surgery.
Trichuris trichiura (whipworm) (pathogenic)	Egg: barrel shaped with 2 clear, polar plugs; adult worm: rarely seen; eggs should be quantitated (rare, few, etc.), since light infections may not be treated.	Dual infections with *A. lumbricoides* may be seen (both infections are acquired from ingestion of eggs from contaminated soil); in severe infections, rectal prolapse may occur in children or bloody diarrhea can be mistaken for amebiasis (these clinical manifestations are usually not seen in the United States).
Enterobius vermicularis (pinworm)	Egg: football shaped with one flattened side; adult worm: about 3/8 in. long, white with pointed tail; female migrates from the anus and deposits eggs on the perianal skin.	Causes itching in some patients. Test of choice is Scotch tape preparation; 4–6 consecutive tapes necessary to rule out infection; symptomatic patients often treated without actual confirmation of infection; eggs become infective within a few hours.
Ancylostoma duodenale (Old World hookworm), *Necator americanus* (New World hookworm) (pathogenic)	Egg: eggs of both species are identical, oval with broadly rounded ends, thin shell, clear space between shell and developing embryo (8–16-cell stage); adult worms: rarely seen in clinical specimens	Causes blood-loss anemia on the differential smear in heavy infections in some patients. If stool remains unpreserved for several hours or days, the eggs may continue to develop and hatch; rhabditiform larvae may resemble those of *Strongyloides stercoralis*.
Strongyloides stercoralis (pathogenic)	Rhabditiform larvae (noninfective) usually found in the stool; short buccal cavity or capsule with large genital primordial packet of cells ("short and sexy"); in very heavy infections, larvae occasionally found in sputum and/or filariform (infective) larvae can be found in stool (slit in the tail)	May cause unexplained eosinophilia, abdominal pain, unexplained episodes of sepsis and/or meningitis, and pneumonia (migrating larvae) in the compromised patient. Potential for internal autoinfection can maintain low-level infections for many years (patient is asymptomatic or has eosinophilia); hyperinfection can occur in the compromised patient (leading to disseminated strongyloidiasis and death); agar plate culture is the most sensitive diagnostic method; many infections are low-level, and larvae are difficult to recover.
Ancylostoma braziliensis (dog or cat hookworm) (pathogenic)	Humans are accidental hosts; larvae wander through the outer layer of skin, creating tracks (causing severe itching and eosinophilia); no practical microbiological diagnostic tests	Cause of cutaneous larva migrans; typical setup for infection is when dogs and cats defecate in sand boxes and hookworm eggs hatch and penetrate human skin when in contact with infected sand or soil (children playing in sand box).
Toxocara cati and *T. canis* (dog and cat ascarid) (pathogenic)	Humans are accidental hosts; infection is by ingestion of dog or cat ascarid eggs in contaminated soil; larvae wander through deep tissues (including the eye); can be mistaken for cancer of the eye; serologic tests helpful for confirmation; infection causes eosinophilia.	Cause of visceral larva migrans, ocular larva migrans, and neural larva migrans; requests for laboratory services often originate in the ophthalmology clinic.
Cestodes (tapeworms)		
Taenia saginata (beef tapeworm)	Scolex (4 suckers, no hooklets) and gravid proglottid (>12 branches on a single side) are diagnostic; eggs indicate *Taenia* spp. only (thick, striated shell containing a 6-hooked embryo or oncosphere); worm usually about 12–15 ft long.	Adult worm causes symptoms in some individuals. Infection occurs via ingestion of raw or poorly cooked beef; usually only a single worm per patient; individual proglottids may crawl from the anus; India ink can be injected into proglottids to visualize the uterine branches for identification.
Taenia solium (pork tapeworm)	Scolex (4 suckers with hooklets) and gravid proglottid (<12 branches on a single side) are diagnostic; eggs indicate *Taenia* spp. only (thick, striated shell containing a 6-hooked embryo or oncosphere); worm is usually about 6–20 ft long.	Adult worm causes gastrointestinal complaints in some individuals; cysticercosis (accidental ingestion of eggs) can cause severe central nervous system symptoms. Infection is via ingestion of raw or poorly cooked pork; usually only a single worm per patient; occasionally 2 or 3 proglottids (hooked together) are passed. India ink can be injected into proglottids to visualize the uterine branches for identification. Cysticerci are normally small and contained within an enclosing membrane; they occasionally develop as the "racemose" type in which the worm tissue grows in the body like a metastatic cancer.

Diphyllobothrium latum (broad fish tapeworm)	Scolex (lateral sucking grooves), gravid proglottid (wider than long, reproductive structures in the center "rosette"); eggs are operculated.	Causes gastrointestinal complaints in some individuals. Infection is via ingestion of raw or poorly cooked freshwater fish; life cycle has 2 intermediate hosts (copepod and fish); worm may reach 30 ft long. Associated with vitamin B_{12} deficiency in genetically susceptible groups (e.g., Scandinavians).
Hymenolepis nana (dwarf tapeworm)	Adult worm not normally seen; egg round to oval, thin shell, containing a 6-hooked embryo or oncosphere with polar filaments lying between the embryo and egg shell.	Causes gastrointestinal complaints in some individuals. Infection is via ingestion of eggs (the only life cycle in which the intermediate host [grain beetle] can be bypassed); life cycle of egg to larval form to adult can be completed in the human. May be the most common tapeworm in the world.
Hymenolepis diminuta (rat tapeworm)	Adult worm not normally seen; egg round to oval, thin shell, containing a 6-hooked embryo or oncosphere without polar filaments lying between the embryo and egg shell.	Uncommon; egg can be confused with *H. nana*. Eggs will be submitted in proficiency-testing specimens and must be differentiated from those of *H. nana*.
Echinococcus granulosus (pathogenic)	Adult worm found only in the carnivore (dog); hydatid cysts develop (primarily in the liver) when humans accidentally ingest eggs of the dog tapeworms; cyst contains daughter cysts and many scolices; laboratory should examine fluid aspirated from cyst at surgery.	Humans are accidental intermediate hosts; the normal life cycle is dog to sheep, with the hydatid cysts developing in the liver, lung, etc., of the sheep. Human hosts may be unaware of their infection unless fluid leaks from the cyst (can trigger an anaphylactic reaction) or pain is felt at the cyst location.
Echinococcus multilocularis (pathogenic)	Adult worm found only in the carnivore (fox or wolf); hydatid cysts develop (primarily in the liver) when humans accidentally ingest eggs of the carnivore tapeworms; cyst grows like a metastatic cancer with no limiting membrane.	Humans are accidental intermediate hosts. Prognosis is poor; surgical removal of the tapeworm tissue is very difficult. Found in Canada, Alaska, and less frequently in the northern United States but is becoming more common in the United States, where the geographic range is moving further south.
Trematodes (flukes)		
Fasciolopsis buski (giant intestinal fluke)	Eggs found in stool; very large and operculated (morphology like that of *F. hepatica* eggs)	Symptoms depend on worm burden; acquired from ingestion of plant material on which metacercariae have encysted (e.g., water chestnuts); worms are hermaphroditic.
Fasciola hepatica (sheep liver fluke)	Eggs found in stool; cannot be differentiated from those of *F. buski*	Symptoms depend on worm burden; acquired from ingestion of plant material on which metacercariae have encysted (e.g., watercress); worms are hermaphroditic.
Clonorchis (*Opisthorchis*) *sinensis* (Chinese liver fluke)	Eggs found in stool; very small (<35 µm); are operculated with shoulders into which the operculum fits	Symptoms depend on worm burden; acquired from ingestion of raw fish. Eggs can be missed unless ×400 power is used for examination; eggs can resemble those of *Metagonimus yokogawai* and *Heterophyes heterophyes* (small intestinal flukes). Worms are hermaphroditic.
Paragonimus spp. (lung fluke)	Eggs coughed up in sputum (brownish "iron filings" are egg packets); can be recovered in sputum or stool (if swallowed); are operculated with shoulders into which operculum fits	Symptoms depend on worm burden and egg deposition. Infection acquired from ingestion of raw crabs. Eggs can be confused with those of *D. latum*. Infections seen in Asia (infections with *P. mexicanus* found in Central and South America). *P. kellicotti* infections (rare) are seen in the United States. Worms are hermaphroditic but often cross-fertilize with another worm if present.
Schistosoma mansoni (blood fluke)	Eggs recovered in stool (large lateral spine); specimens should be collected with no preservatives (to allow demonstration of egg viability); worms in veins of large intestine	Acquired from skin penetration by a single cercaria from the freshwater snail. Pathologic findings are caused by host immune response to the presence of eggs in tissues; adult worms in veins cause no problems. Adult worms are separate sexes.
Schistosoma haematobium (blood fluke)	Eggs recovered in urine (large terminal spine); specimens should be collected with no preservatives (to allow demonstration of egg viability); worms in veins of bladder	Acquired from skin penetration by single cercaria from the freshwater snail; pathologic findings as with *S. mansoni;* 24-h and spot urine samples should be collected. Chronic infection has association with bladder cancer. Adult worms are separate sexes.
Schistosoma japonicum (blood fluke)	Eggs recovered in stool (very small lateral spine); specimens should be collected with no preservatives (to allow demonstration of egg viability); worms in veins of small intestine	Acquired from skin penetration by multiple cercariae from the freshwater snail; pathologic findings as with *S. mansoni;* infection usually the most severe of the 3 species because of original loading dose of infective cercariae from the freshwater snail (multiple cercariae stick together). Symptoms are associated with egg production, which is greatest in *S. japonicum* infections.

---

[b] 1 in. = 2.54 cm; 1 ft = 30.48 cm.

TABLE A1.15 Key characteristics of most common parasites found in blood[a]

Organism	Diagnostic stage	Comments
Protozoa		
Malaria parasites		
Plasmodium vivax (benign tertian malaria)	Ameboid rings; presence of Schüffner's dots, beginning in older rings (appear later than those in *P. ovale*); all stages seen in peripheral blood; mature schizont contains 16–18 merozoites.	Infects young cells; 48-h cycle; large geographic range; tends to have true relapse from the residual liver stages (hypnozoites); enlarged RBCs
Plasmodium ovale (ovale malaria)	Nonameboid rings; presence of Schüffner's dots, beginning in young rings (appear earlier than those in *P. vivax*); all stages seen in peripheral blood; mature schizont contains 8–10 merozoites; RBCs may be oval and have fimbriated edges.	Infects young cells; 48-h cycle; narrow geographic range; tends to have true relapse from residual liver stages (hypnozoites); enlarged RBCs
Plasmodium malariae (quartan malaria)	Thick rings; no stippling; all stages seen in peripheral blood; presence of band forms and rosette-shaped mature schizont; abundant malarial pigment	Infects old cells; 72-h cycle; narrow geographic range; associated with recrudescence and nephrotic syndrome; no true relapse; normal or small RBCs
Plasmodium falciparum (malignant tertian malaria)	Multiple rings; appliqué/accolé forms; no stippling (rare Maurer's clefts); rings and crescent-shaped gametocytes seen in peripheral blood (no other developing stages, with rare exception of mature schizont)	Infects all cells; 36–48-h cycle; large geographic range; no true relapse; most pathogenic of the 4 species; plugged capillaries can cause severe symptoms and sequelae (cerebral malaria, lysis of RBCs, etc.).
Plasmodium knowlesi (simian malaria)	Multiple rings; no stippling; all stages seen in peripheral blood; will mimic *P. falciparum* early in the life cycle, then will mimic *P. malariae* in the later stages; often identified as a mixed infection with those two species	Infects all cells; very rapid cycle of 24 h; small geographic range (Malaysia and neighboring areas); as pathogenic as *P. falciparum;* development in RBCs may be asynchronous; no true relapse
Babesia spp.	Ring forms only (resemble *P. falciparum* rings); seen in splenectomized patients; endemic in the United States (no travel history necessary); if present, Maltese cross configuration is diagnostic but not always seen (more common in West Coast organisms; less common in East Coast, *B. microti*	Tick-borne infection; associated with Nantucket Island; infection mimics malaria; ring forms more pleomorphic than malaria; usually more rings/cell than in malaria; endemic in several areas in the United States (East and West Coasts); organisms occasionally seen outside RBCs (unlike malaria merozoites)
Trypanosomes		
Trypanosoma brucei gambiense (West African sleeping sickness)	Trypomastigotes long, slender, with typical undulating membrane and very tiny kinetoplast; lymph nodes and blood can be sampled; microhematocrit tube concentration helpful; examine spinal fluid in later stages of the infection; elevated IgM	Tsetse fly vector; tends to be chronic infection, causing the real symptoms of sleeping sickness; more chronic infection; division occurs in the trypomastigote stage.
Trypanosoma brucei rhodesiense (East African sleeping sickness)	Trypomastigotes long, slender, with typical undulating membrane; small kinetoplast; lymph nodes and blood can be sampled; microhematocrit tube concentration helpful; examine spinal fluid in later stages of the infection; elevated IgM	Tsetse fly vector; tends to be more severe, short-lived infection (particularly in children); patient may die before progressive symptoms of sleeping sickness appear; division occurs in the trypomastigote stage.
Trypanosoma cruzi (Chagas' disease) (American trypanosomiasis)	Trypomastigotes short, stumpy, often curved in C shape; large kinetoplast; blood sampled early in infection; trypomastigotes enter striated muscle (heart, gastrointestinal tract) and transform into the amastigote form.	Reduviid bug vector (kissing bug); chronic in adults but severe in young children; great morbidity associated with cardiac failure and loss of muscle contractility in heart and gastrointestinal tract; division occurs in the amastigote stage.

Trypanosoma rangeli	Trypomastigotes long, slender, with typical undulating membrane and tiny kinetoplast	Reduviid bug vector; *T. rangeli* infections often overlap with *T. cruzi* infections; in some areas, *T. rangeli* represents 5 or 6 times the number of *T. cruzi* infections; assumed to be nonpathogenic for humans; has been noted in the blood for >1 year; infections with *T. cruzi* and *T. rangeli* can coexist in the reduviid vector.
Leishmaniae		
Leishmania spp. (cutaneous; not actually a blood parasite but presented for comparison with *L. donovani*)	Amastigotes found in macrophages of skin; presence of intracellular forms containing nucleus and bar-shaped kinetoplast is diagnostic.	Sand fly vector; organisms recovered from site of lesion only; specimens can be stained or cultured in NNN[b] and/or Schneider's medium; animal (hamster) inoculation rarely used
Leishmania braziliensis and other *Leishmania* spp. (mucocutaneous; not actually a blood parasite but presented for comparison with *L. donovani*)	Amastigotes found in macrophages of skin and mucous membranes; presence of intracellular forms containing nucleus and bar-shaped kinetoplast is diagnostic.	Sand fly vector; organisms recovered from site of lesion only; specimens can be stained or cultured in NNN and/or Schneider's medium; animal (hamster) inoculation rarely used
Leishmania donovani and other *Leishmania* spp. (visceral)	Amastigotes found throughout the reticuloendothelial system (spleen, liver, bone marrow, etc.); presence of intracellular forms containing nucleus and bar-shaped kinetoplast diagnostic; patients have hypergammaglobulinemia	Sand fly vector; organisms recovered from buffy coat monocytes (rarely found), bone marrow aspirate, spleen or liver puncture (rarely performed); specimens can be stained or cultured in NNN and/or Schneider's medium; animal (hamster) inoculation rarely used; cause of kala azar
Helminths		
Wuchereria bancrofti	Microfilariae sheathed, clear space at end of tail; nocturnal periodicity seen; elephantiasis seen in chronic infections	Pathogenicity due to presence of adult worms; mosquito vector; microfilariae recovered in blood (membrane filtration, Knott concentrate, thick films); hematoxylin stains the sheath; Giemsa stain does not stain the sheath.
Brugia malayi	Microfilariae sheathed, subterminal and terminal nuclei at end of tail; nocturnal periodicity seen; elephantiasis seen in chronic infections	Pathogenicity due to presence of adult worms; mosquito vector; microfilariae recovered in blood (membrane filtration, Knott concentrate, thick films); hematoxylin stains the sheath; Giemsa stains the sheath pink; sheath of *B. timori* does not stain with Giemsa.
Loa loa (African eye worm)	Microfilariae sheathed, nuclei continuous to tip of tail; diurnal periodicity; adult worm may cross the conjunctiva of the eye.	Pathogenicity due to presence of adult worms; mango fly vector; history of calabar swellings, worms in the eye; microfilariae difficult to recover from blood; hematoxylin stains the sheath; Giemsa stain does not stain the sheath.
Mansonella spp.	Microfilariae unsheathed, nuclei may or may not extend to tip of tail (depending on species); nonperiodic; symptoms usually absent or mild	Pathogenicity mild and due to presence of adult worms; midge or blackfly vector; microfilariae recovered in blood (membrane filtration, Knott concentrate, thick films); hematoxylin and Giemsa stain characteristics identical
Mansonella streptocerca	Microfilariae unsheathed, nuclei extend to tip of tail; when immobile, curved like shepherd's crook; adults in dermal tissues	Pathogenicity mild and due to presence of adult worms and/or microfilariae; midge vector; microfilariae found in skin snips; microfilarial tails are split rather than blunt; hematoxylin and Giemsa stain characteristics identical
Onchocerca volvulus	Microfilariae unsheathed, nuclei do not extend to tip of tail; adults in nodules	Pathogenicity due to presence of microfilariae; blackfly vector; microfilariae found in skin snips; microfilariae migrate to optic nerve; cause of river blindness

TABLE A1.16 Diagnostic laboratory report information that should be relayed to the physician[a]

Organisms and other findings	Genus and species	Life cycle stages	Quantitation[b]	Pathogenic/ nonpathogenic	Viable/nonviable
Protozoa					
Intestinal	Yes	Yes (C, T)	No	Both	NA[c]
Blastocystis spp.		NA	Yes	Pathogenicity comment	NA
Tissue	Yes	NA	No	NA	NA
Blood	Yes	Yes (G)	Yes	NA	NA
Genitourinary tract	Yes	NA	No	NA	NA
Trematodes					
Intestinal	Yes	NA	Yes	NA	NA
Liver	Yes	NA	Yes	NA	NA
Lungs	Yes	NA	Yes	NA	NA
Blood	Yes	NA	Yes	NA	Egg viability
Cestodes					
Intestinal	Yes	Yes (E, P)	NA	NA	NA
Tissue	Yes	NA	NA	NA	NA
Nematodes					
Intestinal	Yes	NA	Rarely[d]	NA	NA
Filarial	Yes	NA	Yes	NA	NA
Nonparasitic					
Yeast	NA	Yes[e]	Yes	NA	NA
Human cells (WBCs, RBCs)	NA	NA	Yes	NA	NA
Crystals (C-L, barium)	NA	NA	Yes	NA	NA

[a] C, cyst; C-L, Charcot-Leyden; E, egg; G, gametocyte; P, proglottid; RBC, red blood cell; T, trophozoite; WBC, white blood cell.

[b] May require numbers of infected cells, eggs, etc. (either as specific count or as rare, few, moderate, or many).

[c] NA, not applicable.

[d] If *Trichuris trichiura* eggs are rare or few, the infection may not be treated.

[e] The specimen must be fresh and should be examined immediately; alternatively, it should be freshly preserved in a stool collection kit *by the patient* (no lag time between stool passage and preservation); if these requirements are not met, the report (presence of budding yeasts and/or pseudohyphae or hyphae) may be misleading and should not be reported to the physician. Report budding yeast cells and/or the presence of pseudohyphae or hyphae as a consult with physician (not routinely reported; may be misleading).

TABLE A1.17 Pros and cons of stool specimen collection and testing options[a]

Option[b]	Pros	Cons
Rejection of stools from inpatients who have been in-house for >3 days	Data suggest that patients who begin to have diarrhea after they have been inpatients for a few days are not symptomatic from parasitic infections, but generally from other causes.	There is always the chance that the problem is related to a health care-associated (nosocomial) parasitic infection (rare), but *Cryptosporidium* and microsporidia are possible considerations.
Examination of 1 stool (O&P examination)	Data suggest that 40–50% of organisms present will be found with only 1 stool exam. Some feel that most intestinal parasitic infections can be diagnosed from examination of a single stool. If the patient becomes asymptomatic after collection of the first stool, subsequent specimens may not be necessary.	Diagnosis from examination of a single specimen depends on the experience of the microscopist, proper collection, and the parasite load in the specimen. In a series of 3 stool specimens, frequently not all 3 specimens are positive and/or may be positive for different organisms.
Use of 2 O&P exams (concentration, permanent stained smear)	The examination of 2 specimens is more sensitive than 1 examination; different organisms may be found in the 2 specimens; 1 might be negative while 1 is positive.	May not be as cost-effective as examination of 1 specimen. Not always as good as examination of 3 specimens (may be a relatively cost-effective approach); any patient remaining symptomatic would require additional testing.
Examination of a second stool specimen only after the first is negative and the patient is still symptomatic	With additional examinations, the yield of protozoa increases (*Entamoeba histolytica*, 22.7%; *Giardia lamblia*, 11.3%; *Dientamoeba fragilis*, 31.1%)	Assumes that the second (or third) stool is collected within the recommended 10-day time frame for a series of stools; protozoa are shed periodically. May be inconvenient for patient.
Examination of 1 stool specimen and an immunoassay (EIA, FA, lateral- or vertical-flow cartridge)	If the examinations are negative and the patient's symptoms subside, probably no further testing is required.	This approach is a mix: 1 immunoassay may be acceptable; however, immunoassay testing of 2 separate specimens may be required to confirm the presence of *Giardia* antigen. One O&P exam is not the best approach (review the last option below). Patients may exhibit symptoms (off and on), so it may be difficult to rule out parasitic infections. If the patient remains symptomatic, even if 2 *Giardia* immunoassays are negative, other protozoa may be missed (the *Entamoeba histolytica/E. dispar* group, *E. histolytica*, *Dientamoeba fragilis*, *Cryptosporidium* spp., the microsporidia). Normally, there are specific situations where fecal immunoassays or O&P exams should be ordered. It is not recommended to automatically perform both the O&P and fecal immunoassay as a stool exam for parasites (see Table A1.18). **Depending on the patient's history and clinical symptoms, EITHER the O&P exam OR a fecal immunoassay may be recommended, BUT GENERALLY NOT BOTH.**
Pool 3 specimens for examination; perform 1 concentration and 1 permanent stain	Three specimens are collected by the patient (3 separate collection vials) over 7–10 days; pooling by the laboratory may save time and expense.	Organisms present in small numbers may be missed due to the dilution factor once the specimens are pooled.
Pool 3 specimens for examination; perform 1 concentration and 3 permanent stained smears	Three specimens are collected by the patient (3 separate collection vials) over 7–10 days; pooling by the laboratory for the concentration would probably be sufficient for the identification of helminth eggs. Examination of the 3 separate permanent stained smears (1 from each vial) would maximize recovery of intestinal protozoa in areas of the country where these organisms are most common.	Might miss light helminth infection (eggs, larvae) due to the pooling of the 3 specimens for the concentration; however, with a permanent stain performed on each of the 3 specimens, this approach would probably be the next best option to the standard approach (concentration and permanent stained smear performed on every stool). Coding and billing would have to match the work performed; this may present some problems where work performed does not match existing codes and billing. Per standard recommendations and CAP, O&P must include the concentration and permanent stained smear.

(continued)

TABLE A1.17 Pros and cons of stool specimen collection and testing options[a] *(continued)*

Option[b]	Pros	Cons
Collection of 3 stools by the patient, with all 3 samples put into a single vial (patient given a single vial only)	Pooling of the specimens would require only a single vial.	This would complicate patient collection and very likely result in poorly preserved specimens, especially regarding the recommended ratio of stool to preservative and the lack of proper mixing of specimen and fixative.
Immunoassays performed for selected patients,[c] using methods for *G. lamblia*, *Cryptosporidium* spp., and/or the *E. histolytica/E. dispar* group or *E. histolytica*	Would be more cost-effective than performing immunoassay procedures on all specimens; however, information required to group patients is often not received with specimens. *This approach assumes that the physicians have guidance in terms of correct ordering options (see Table A1.18).*	Laboratories rarely receive information that would allow them to place a patient in a particular risk group: children <5 yr old, children from day care centers (may or may not be symptomatic), patients with immunodeficiencies, and patients from outbreaks. Performance of immunoassay procedures on every stool sample is not cost-effective, and the positive rate will be low unless an outbreak situation is involved.
Immunoassays and O&P exams performed on request using methods for *G. lamblia*, *Cryptosporidium* spp., and/or *E. histolytica/E. dispar* group or *E. histolytica* (a number of variables will determine the approach to immunoassay testing and the O&P exam [geography, parasites recovered, positive rate, physician requests]; immunoassays and/or O&P exams should be separately ordered, reported, and billed)	This approach limits the number of stools on which immunoassay procedures are performed for parasites. Immunoassay results do not have to be confirmed by any other tests (such as O&P exams or modified acid-fast stains). If specific kit performance problems have been identified, individual laboratories may prefer to do additional testing. *However, the fecal immunoassays are more sensitive than the O&P exam and special stains (modified acid-fast stains).* Also, this may be considered duplicate testing and may not be approved for reimbursement unless specifically ordered by the physician.	Requires education of the physician clients regarding appropriate times and patients for whom fecal immunoassays should be ordered. Educational initiatives must also include information on the test report indicating the pathogenic parasites that will not be detected by these methods. It is critical to ensure that clients know that if patients have become asymptomatic, further testing may not be required. *However, if the patient remains symptomatic, further testing (O&P exams) is required*. Remember, a single O&P exam may not reveal all organisms present. Present plan to physicians for approval: immunoassays or O&P exams, procedure discussion, report formats, clinical relevance, and limitations on each approach.

[a] For further information, see the following papers: Hiatt RA, et al, *Am J Trop Med Hyg* **53**:36–39, 1995; Kehl KSC, *Clin Microbiol Newsl* **18**:133–135, 1996; Morris AJ, et al, *J Clin Microbiol* **30**:3213–3216, 1992; Siegel DL, et al, *JAMA* **263**:979–982, 1990.

[b] O&P exam, ova and parasite examination; EIA, enzyme-linked immunoassay; FA, fluorescent-antibody immunoassay; CAP, College of American Pathologists.

[c] It is difficult to know when you may be in an early-outbreak situation where testing of all specimens for either *Giardia lamblia* or *Cryptosporidium* spp., or both, may be relevant. Extensive efforts are under way to encourage communication among laboratories, water companies, pharmacies, and public health officials regarding the identification of potential or actual outbreaks. If it appears that an outbreak is in the early stages, then performing the immunoassays on request can be changed to screening all stools.

TABLE A1.18 Approaches to stool parasitology: test ordering

Patient and/or situation	**Test ordered**[a]	**Follow-up test ordered**
♦ Patient with diarrhea and AIDS or other cause of immune deficiency ♦ Potential waterborne outbreak (municipal/city water supply)	*Cryptosporidium* or *Giardia/Cryptosporidium* immunoassay	If immunoassays are negative and symptoms continue, special tests for microsporidia (modified trichrome stain) and other coccidia (modified acid-fast stain) and O&P exam should be performed.
♦ Patient with diarrhea (nursery school, day care center, camper, backpacker) ♦ Patient with diarrhea and potential waterborne outbreak (resort setting) ♦ Patient with diarrhea from areas where *Giardia* is the most common parasite found	*Giardia* or *Giardia/Cryptosporidium* immunoassay (perform testing on two stools before reporting as negative) **Particularly relevant for areas of the U.S. where *Giardia* is the most common organism found**	If immunoassays are negative and symptoms continue, special tests for microsporidia and other coccidia (see above) and O&P exam should be performed.
♦ Patient with diarrhea and relevant travel history outside the United States ♦ Patient with diarrhea who is a past or present resident of a developing country ♦ Patient in an area of the United States where parasites **other than *Giardia*** are found (large metropolitan areas like Los Angeles, New York, Boston, Miami, etc.)	O&P exam,[b] *Entamoeba histolytica/E. dispar* immunoassay; immunoassay for confirmation of *E. histolytica*; various tests for *Strongyloides* may be relevant (even in the absence of eosinophilia), particularly if there is any history of pneumonia (migrating larvae in lungs), sepsis, or meningitis (fecal bacteria carried by migrating larvae); agar culture plate is the most sensitive diagnostic approach for *Strongyloides*.	The O&P exam is designed to detect and identify a broad range of parasites (amebae, flagellates, ciliates, *Cystoisospora belli*, helminths); if exams are negative and symptoms continue, special tests for coccidia (fecal immunoassays, modified acid-fast stains, autofluorescence) and microsporidia (modified trichrome stains, calcofluor white stains) should be performed; fluorescent stains are also options.
♦ Patient with unexplained eosinophilia and possible diarrhea; if chronic, patient may also have history of respiratory problems (larval migration) and/or sepsis or meningitis (hyperinfection)	Although the O&P exam is recommended, the agar plate culture for *Strongyloides stercoralis* (more sensitive than the O&P exam) is also recommended, particularly if there is any history of pneumonia (migrating larvae in lungs), sepsis, or meningitis (fecal bacteria carried by migrating larvae).	If tests are negative and symptoms continue, additional O&P exams and special tests for microsporidia (modified trichrome stains, calcofluor white stains, fluorescent stains) and other coccidia (modified acid-fast stains, autofluorescence, fluorescent stains) should be performed; serology for *Strongyloides* may also be recommended.
♦ Patient with diarrhea (suspected food-borne outbreak)	Test for *Cyclospora cayetanensis* (modified acid-fast stain, autofluorescence, fluorescent stains)	If tests are negative and symptoms continue, special procedures for microsporidia and other coccidia and O&P exam should be performed.

[a] Depending on the particular immunoassay kit used, various single or multiple organisms may be included. Selection of a particular kit depends on many variables: clinical relevance, cost, ease of performance, training, personnel availability, number of test orders, training of physician clients, sensitivity, specificity, equipment, time to result, etc. Very few laboratories will handle this type of testing exactly the same. Many options are clinically relevant and acceptable for good patient care. It is critical that the laboratory report indicate specifically which organisms could be identified using the kit; a negative report should list the organisms relevant to that particular kit. It is important to remember that sensitivity and specificity data for all of these fecal immunoassay kits (fluorescent-antibody assay, enzyme immunoassay, cartridge formats) are comparable.

[b] O&P exam, ova and parasite examination.

TABLE A1.19 Pros and cons of ova and parasite examination options[a]

Testing option[b]	Pros	Cons
Stools from patients who have been inpatients for at least 3 days should not be submitted for routine examinations without consulting the laboratory.	Normally, only very few parasitic infections can be acquired by an inpatient. Although rare, one of these infections is cryptosporidiosis, which has been documented in nosocomial transmission.	Etiologic agents other than parasites, as well as other causes such as therapy, are more likely to cause diarrhea in patients who have been hospitalized for 3 days or more. There are always exceptions, but this is a reasonable guideline to follow (see Table A1.17).
3 separate stools collected within 10 days; concentration and permanent stained smear on all specimens; if specimen is fresh (unpreserved), direct wet smear can be performed (soft, liquid specimens) for the detection of organism motility	Maximize recovery of all organisms, including those in small numbers; concentration for recovery of protozoan cysts, helminth eggs, and larvae; permanent stain for confirmation of protozoa and finding protozoa missed on concentration wet examination. Special stains or immunoassay reagents may be used for the recovery of coccidia and microsporidia.	Although this approach is the most labor intensive, the results are the most complete.[c] According to recommendations (CLSI, Cumitechs, College of American Pathologists Microbiology Checklist) an O&P must include the concentration and permanent stain to be coded/billed as an O&P examination.
3 separate stools collected within 10 days; concentration on pooled specimen, permanent stained smear on all specimens (performed as 3 separate examinations)	By pooling 3 specimens and performing one concentration and examination, time is saved. Since intestinal protozoa tend to be the most common parasites found in many areas of the United States, it is important to perform permanent stained smears on the 3 individual specimens.	If helminth eggs or larvae are present in small numbers, they may be missed. Protozoa that may be missed in small numbers will probably be identified on the individual permanent stained smears.
1 stool; concentration and permanent stained smear; additional specimens may be examined after results of the first specimen are reported	Saves time	Organisms present in small numbers may be missed; the collection of specimens 2 or 3 may be outside the 10-day recommended time frame. The series of 3 specimens now becomes 3 series of a single specimen (depending on collection time frames).[c]
1 stool; *Giardia* and *Cryptosporidium* immunoassay[d]	This can be ordered after complete discussion with physicians so that they recognize what the results (negative) mean in terms of limitations; if negative with a patient who continues to be symptomatic, ova and parasite examinations can be ordered. In areas where *Giardia lamblia* is commonly found or in a suspect waterborne outbreak (*Cryptosporidium* or other organisms), this is an acceptable option. However, it is now clear that 2 specimens may have to be examined to confirm the presence of giardiasis (this is not applicable for cryptosporidiosis).	If complete information on the relevance of a negative report is not given to the physician, this approach can be used incorrectly. It is very important that immunoassay procedures be thoroughly discussed in terms of the clinical relevance of results and the specificity and sensitivity of the methods (more sensitive than the routine ova and parasite examination).
1 stool; concentration performed; permanent stained smear performed *only* if something suspicious is seen on the concentration examination	This approach is thought to save time; however, it is unacceptable both technically and in terms of quality patient care.	Numerous studies have confirmed the importance of the permanent stain, not only in confirming the identification of intestinal protozoa *but also in finding organisms that were missed in the concentration examination*. Use of this technical approach leads to very misleading reported results and should be discouraged. If a laboratory is using this approach, the specimens for parasitology testing should be sent to another laboratory.

Examination approach Direct wet smear: unpreserved soft or liquid stools; total 22- by 22-mm coverslip with 10× objective (low power); 1/4–1/3 of area with 40× objective (high dry power) Concentration: total 22- by 22-mm coverslip with 10× objective (low power); 1/4–1/3 of area with 40× objective (high dry power) Permanent stained smear: minimum of 300 fields with 100× objective (oil immersion); a 50× or 60× oil immersion lens can also be used in the examination process, but some small organisms will be missed without the use of the 100× oil immersion lens.	This represents the most complete approach; however, the important point is to understand the pros and cons of any modifications to this approach. The most common change is the transition from fresh, unpreserved specimens being submitted to the laboratory to fecal specimens that are transported in fixatives. Once received by the laboratory, the direct wet smear is eliminated from the standard ova and parasite procedure (no motility is visible in preserved specimens) and only the concentration and permanent stained smear are performed.	Any modification(s) from the recommended procedures *must* be discussed thoroughly with your physician clients. It is critical that they understand the advantages and disadvantages of each approach. Information can be transmitted through various communication channels: telephone, newsletters, information updates, in-service presentations, verbal and written reminders, information via computer system, etc.

---

[a] **It is mandatory that the physicians know exactly what procedures are performed for the diagnosis of parasitic infections in your specific laboratory and how the results should be interpreted in terms of clinical relevance. It is mandatory that they be given information regarding the pros and cons (limitations) of any diagnostic approach. The complete ova and parasite examination includes direct wet smear, concentration, and permanent stained smear (fresh specimen) or concentration and permanent stained smear (preserved specimen).**

[b] A direct wet smear of fresh specimens (soft or liquid) should be examined for motile trophozoites. If the specimen is formed or is received in preservative, eliminate the direct wet smear examination and proceed directly to the concentration and permanent stained smear.

[c] An excellent reference is Hiatt RA, et al, *Am J Trop Med Hyg* 53:36–39, 1995. **The sensitivity of one stool examination was compared with that of three examinations. The additional examinations increased the percent positive results as follows: 22.7% increase for *Entamoeba histolytica*, 11.3% increase for *Giardia lamblia*, and 31.1% increase for *Dientamoeba fragilis*. Even in symptomatic patients, these data indicate that examination of a single stool specimen will miss a large number of infections by pathogenic protozoa.**

[d] The ova and parasite examination and specific immunoassays should be separate, orderable, billable tests.

TABLE A1.20 Laboratory test reports: optional comments[a,b]

---

1. ***Entamoeba histolytica/E. dispar* group**

   - Unless we see trophozoites containing ingested red blood cells (true pathogen: *E. histolytica*), we cannot tell from the organism morphology whether the patient has actual pathogenic *E. histolytica* organisms or nonpathogenic *E. dispar* present. Report as seen above: *Entamoeba histolytica/E. dispar* group (the word "group" is optional).

   Additional computer comments:

   - *Entamoeba* complex; unable to rule out the true pathogen, *E. histolytica*.
   - Unable to determine pathogenicity from organism morphology.
   - Unable to rule out true pathogen, *Entamoeba histolytica*.
   - Depending on patient's clinical condition, treatment may be appropriate.

   If you have the kit reagents to differentiate the two organisms,[c] comments could also be added:

   - If you wish to determine which of the two organisms is present, please submit a fresh stool specimen.
   - To determine the presence or absence of pathogenic *Entamoeba histolytica*, submit a fresh stool specimen.

2. **Identification of nonpathogens**

   Comments that can be used for reporting nonpathogens include the following. However, *these statements assume that a complete stool exam was performed on multiple stools*; you may detect nonpathogens in the first examination or an incomplete examination but miss a pathogen [example: *Dientamoeba fragilis* (pathogenic) requires the permanent stained smear for identification].

   Additional computer comments:

   - Considered nonpathogenic; treatment not recommended.
   - Nonpathogen; however, indication that patient has ingested something contaminated with fecal material.

3. **Reporting *Blastocystis* spp.**

   Several comments are optional for reporting *Blastocystis* spp.

   - Comprising approximately 20 subtypes/species, half of which are pathogenic, half of which are nonpathogenic.
   - Pathogenicity cannot be determined by morphology.

   You may want to add a second comment:

   - Other organisms capable of causing diarrhea should also be ruled out.

4. **Reporting *Plasmodium* spp.**[d]

   If no organisms are seen:

   - Submission of a single blood specimen will not rule out malaria; submit additional bloods every 4–6 h for 3 days if malaria remains a consideration.

   If *Plasmodium* spp. are detected but you are unable to identify to the species level, report as follows.

   - *Plasmodium* spp. seen, unable to rule out *P. falciparum* or *P. knowlesi*.

   If *Plasmodium* spp. are detected in a possible mixed infection:

   - *Plasmodium* spp. seen, unable to rule out *P. falciparum* or *P. knowlesi*.

   If *P. malariae* or *P. falciparum* is identified:

   - Unable to rule out *P. knowlesi*; confirm travel history to Malaysia or neighboring areas.

   Negative for parasites using automated hematology instruments:

   - Automated hematology instruments will not detect low malaria parasitemias seen in immunologically naive patients (travelers).

---

[a] It is important to remember that educational information for your clients is critical to the success of your test-reporting formats. The information in the table should be shared with your clients prior to changing your actual reporting formats. Your physician group may have a preference regarding additional comments. Information updates or newsletters are appropriate for this purpose.

[b] All of the comments in the table are optional, and wording can be changed to fit your circumstances. However, it is recommended that you select specific comments and try not to use "free text," so that everyone reports test results in the same way each time.

[c] It is important to remember that current fecal immunoassay kits for the detection of the *Entamoeba histolytica/E. dispar* group or differentiation between the true pathogen (*E. histolytica*) and the nonpathogen (*E. dispar*) require fresh or frozen fecal specimens; although preserved specimens (generally formalin base or some of the single-vial fixatives, Universal Fixative/no formalin/no mercury/no PVA/TOTAL-FIX) can be used for the fecal immunoassays for *Giardia lamblia* or *Cryptosporidium* spp., they cannot be used for *Entamoeba* spp. testing.

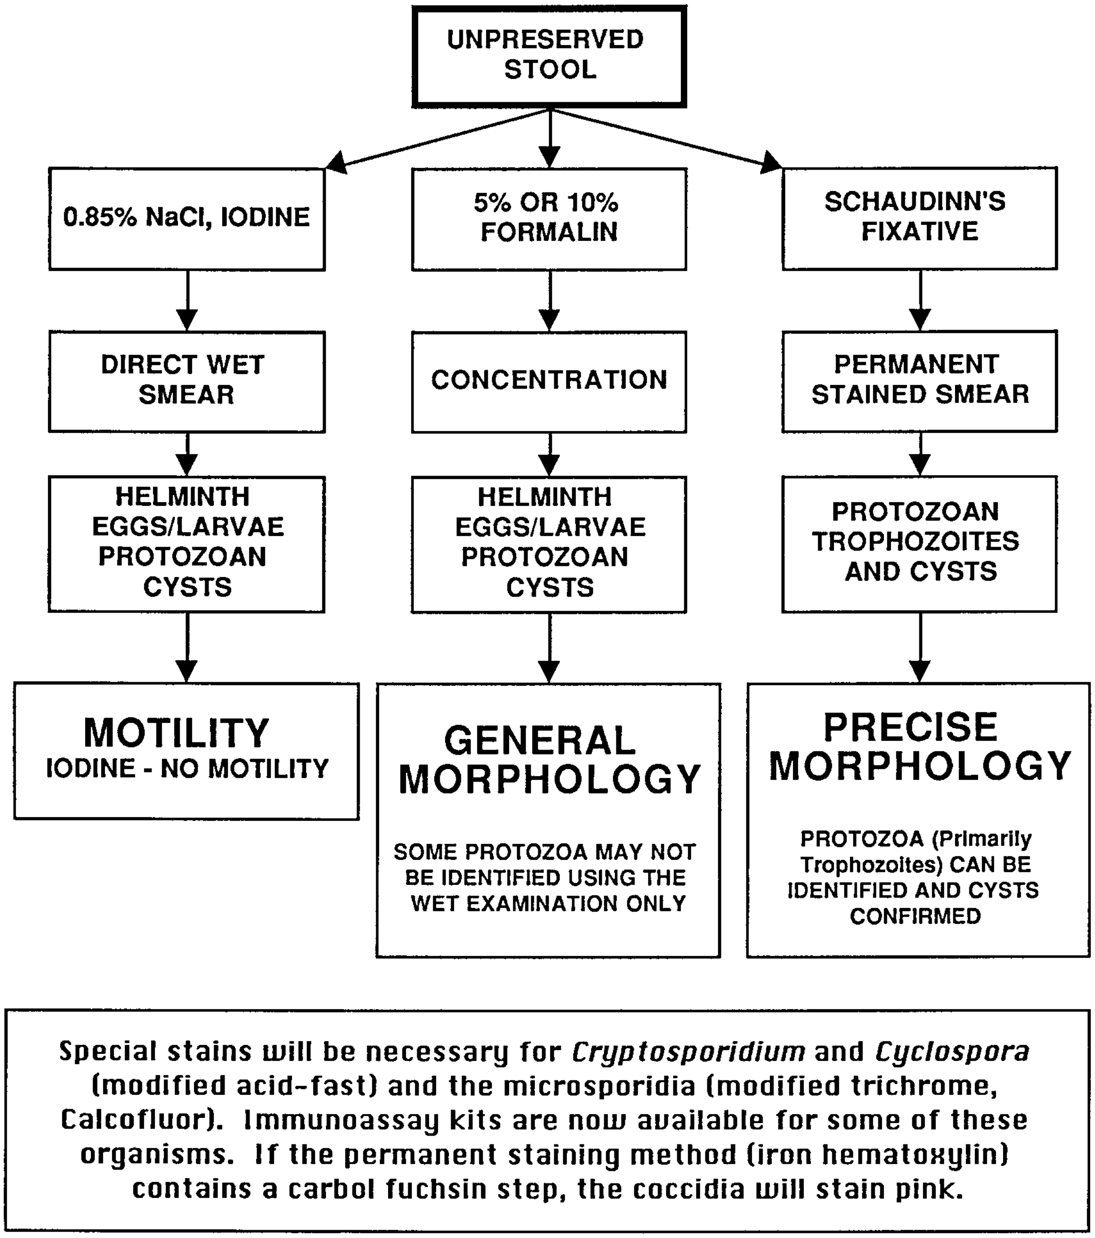
[d] **Note** Use of the BinaxNOW (Alere) malaria rapid test may help detection of mixed infections (STAT test). This test is FDA approved and the external malaria control is now also available (BinaxNOW Malaria Product Fact Sheet Test Kit & Positive Control). However, if test is negative, thick and thin blood film examination is mandatory (STAT).

TABLE A1.21 Estimated prevalence of parasitic diseases worldwide

Disease	Estimated prevalence figures
Protozoa	
Amebiasis	1% of population; annual deaths, 40,000–110,000
Giardiasis	200 million infected
Helminths (nematodes)	
Ascariasis	1.3 billion infected; annual deaths, 1,550; 320 million (35%) school-age children
Hookworm	1.3 billion infected; 233 million (25%) school-age children
Trichuriasis	900 million infected; 239 million (26%) school-age children
Strongyloidiasis	35 million infected
Trichostrongyliasis	5.5 million infected
Dracunculiasis	<100,000 infected
Helminths (cestodes)	65 million infected
Helminths (trematodes)	
Schistosomiasis	200 million infected; 500 million–600 million at risk
S. haematobium	100 million; 56 million (Africa only)
S. mansoni	60 million; 25 million (Africa only)
S. japonicum	1.5 million; annual deaths for all species, 500,000–1 million
Clonorchiasis and opisthorchiasis	13.5 million infected
Paragonimiasis	2.1 million infected
Fasciolopsiasis	10 million infected
Helminths (filiarial infections)	
Lymphatic filariasis	128 million infected; >40 million seriously incapacitated or disfigured; one-third of the people infected with the disease live in India, one-third are in Africa, and most of the remainder are in South Asia, the Pacific, and the Americas
Onchocerciasis	17.7 million infected
Blood parasites	
Malaria	400 million–490 million; annual deaths, 2.2 million–2.5 million; 40% of world's population at risk (3.2 billion); 853,000 deaths/yr in children <5 yr old (fifth leading cause of death in this age group)
Leishmaniasis	12 million infected; 1.5 million–2 million new cases each year; 90% are in 5 countries (Bangladesh, Brazil, India, Nepal, and Sudan); 90% of all cases of mucocutaneous leishmaniasis occur in Bolivia, Brazil, and Peru; 90% of all cases of cutaneous leishmaniasis occur in Afghanistan, Brazil, Iran, Peru, Saudi Arabia, and Syria, with 1 million–1.5 million new cases reported annually worldwide
African trypanosomiasis	300,000–500,000; 100,000 new cases each year; annual deaths, 5,000
American trypanosomiasis	24 million infected; 60,000 annual deaths

APPENDIX 2

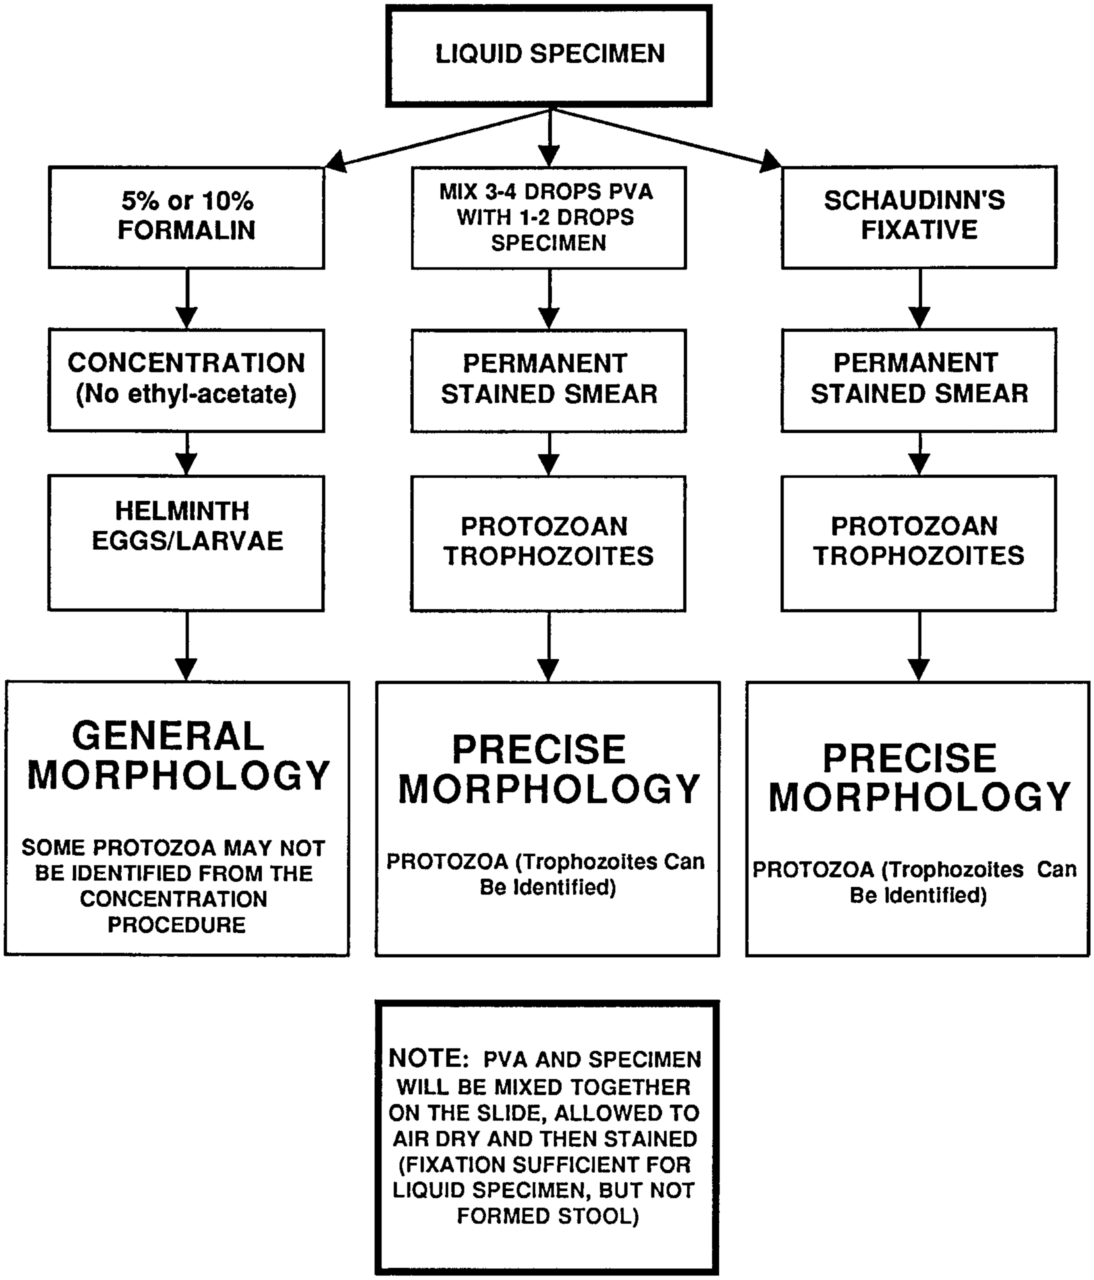
Flowcharts and Staining Tables for Diagnostic Procedures



UNPRESERVED STOOL
0.85% NaCl, IODINE
5% OR 10% FORMALIN
SCHAUDINN'S FIXATIVE
DIRECT WET SMEAR
CONCENTRATION
PERMANENT STAINED SMEAR
HELMINTH EGGS/LARVAE PROTOZOAN CYSTS
HELMINTH EGGS/LARVAE PROTOZOAN CYSTS
PROTOZOAN TROPHOZOITES AND CYSTS
MOTILITY
IODINE - NO MOTILITY
GENERAL MORPHOLOGY
SOME PROTOZOA MAY NOT BE IDENTIFIED USING THE WET EXAMINATION ONLY
PRECISE MORPHOLOGY
PROTOZOA (Primarily Trophozoites) CAN BE IDENTIFIED AND CYSTS CONFIRMED

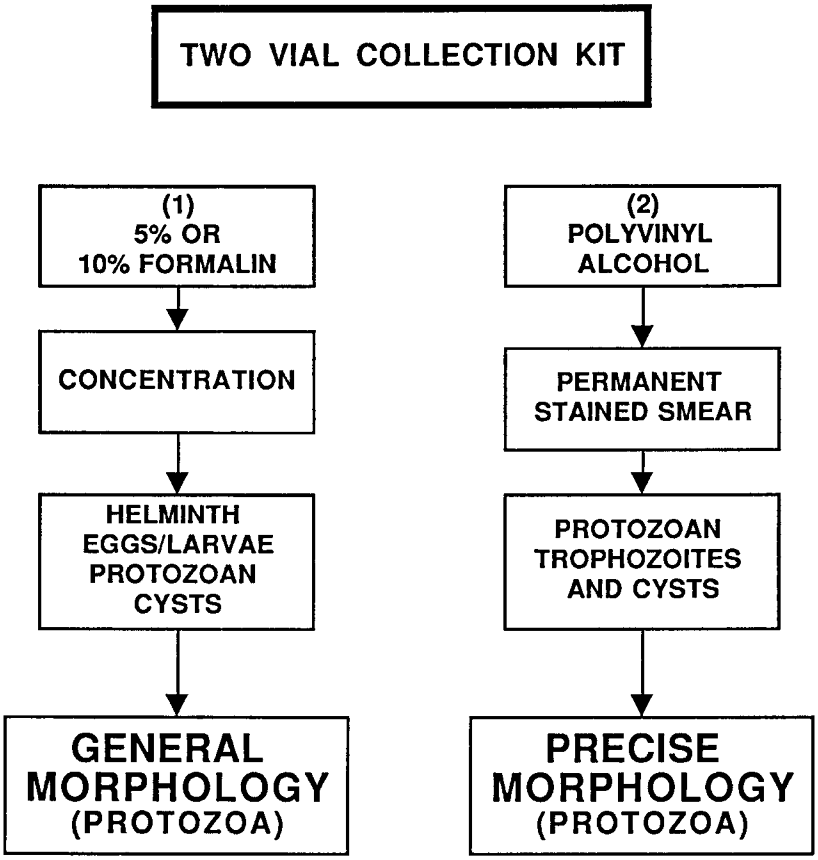
Special stains will be necessary for *Cryptosporidium* and *Cyclospora* (modified acid-fast) and the microsporidia (modified trichrome, Calcofluor). Immunoassay kits are now available for some of these organisms. If the permanent staining method (iron hematoxylin) contains a carbol fuchsin step, the coccidia will stain pink.

Flowchart A2.1 Procedure for processing fresh stool for the ova and parasite examination. Schaudinn's fixative can be prepared using the mercuric chloride base or the zinc sulfate base; the copper sulfate base does not produce organism morphologic quality equal to that seen with the mercuric chloride or zinc sulfate bases. The permanent stained smear can be stained using iron hematoxylin or trichrome stains. This approach includes the direct wet smear, concentration, and the permanent stained smear (complete ova and parasite examination for fresh specimen that is liquid or very soft).



LIQUID SPECIMEN
5% or 10% FORMALIN
MIX 3-4 DROPS PVA WITH 1-2 DROPS SPECIMEN
SCHAUDINN'S FIXATIVE
CONCENTRATION (No ethyl-acetate)
PERMANENT STAINED SMEAR
PERMANENT STAINED SMEAR
HELMINTH EGGS/LARVAE
PROTOZOAN TROPHOZOITES
PROTOZOAN TROPHOZOITES
GENERAL MORPHOLOGY
SOME PROTOZOA MAY NOT BE IDENTIFIED FROM THE CONCENTRATION PROCEDURE
PRECISE MORPHOLOGY
PROTOZOA (Trophozoites Can Be Identified)
PRECISE MORPHOLOGY
PROTOZOA (Trophozoites Can Be Identified)
NOTE: PVA AND SPECIMEN WILL BE MIXED TOGETHER ON THE SLIDE, ALLOWED TO AIR DRY AND THEN STAINED (FIXATION SUFFICIENT FOR LIQUID SPECIMEN, BUT NOT FORMED STOOL)

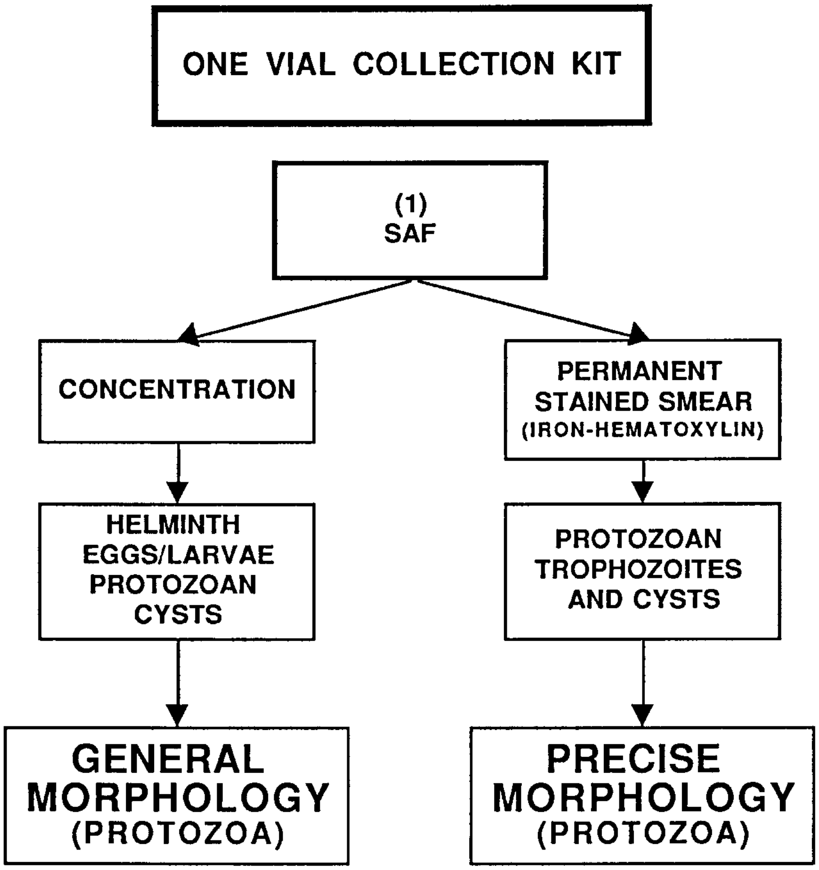
Flowchart A2.2 Procedure for processing liquid specimens for the ova and parasite examination. If the volume of the liquid stool is quite small, mixing some of the specimen with polyvinyl alcohol (PVA) fixative (Schaudinn's fixative or other fixative containing PVA plastic powder that serves as the adhesive to "glue" the fecal material onto the glass slide) directly on the slide is recommended. Make sure that the slide is thoroughly dry before staining. NOTE: PVA FIXATIVE REFERS TO ANY LIQUID FIXATIVE INTO WHICH PVA PLASTIC POWDER HAS BEEN ADDED AS AN ADHESIVE TO "GLUE" THE FECAL MATERIAL ONTO THE SLIDE.



TWO VIAL COLLECTION KIT
(1)
5% OR
10% FORMALIN
CONCENTRATION
HELMINTH
EGGS/LARVAE
PROTOZOAN
CYSTS
GENERAL
MORPHOLOGY
(PROTOZOA)
(2)
POLYVINYL
ALCOHOL
PERMANENT
STAINED SMEAR
PROTOZOAN
TROPHOZOITES
AND CYSTS
PRECISE
MORPHOLOGY
(PROTOZOA)

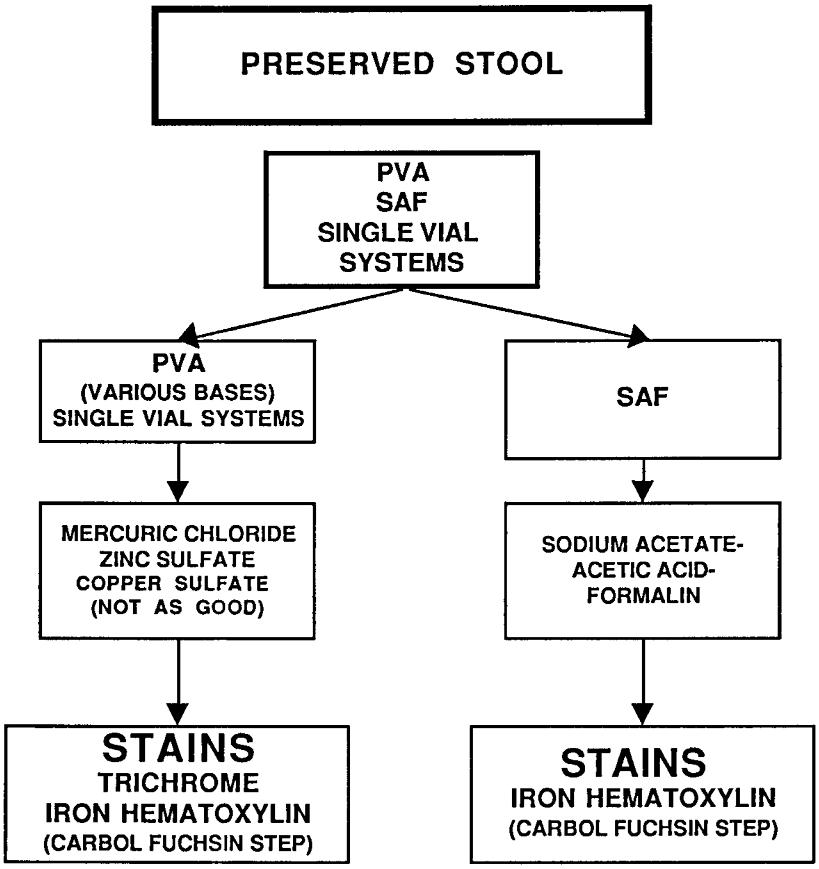
1. **MERCURIC CHLORIDE BASE: BEST PVA**
   (TRICHROME, IRON HEMATOXYLIN)
2. **ZINC BASE: CURRENT BEST SUBSTITUTE**
   (TRICHROME, IRON HEMATOXYLIN PROBABLY OK)
3. **COPPER SULFATE BASE: FAIR SUBSTITUTE**
   (TRICHROME, IRON HEMATOXYLIN - BOTH FAIR-POOR)
4. **SAF: GOOD SUBSTITUTE FOR PVA FIXATIVE**
   (IRON HEMATOXYLIN BEST, TRICHROME OK)

Flowchart A2.3 Procedure for processing preserved stool for the ova and parasite examination by using the traditional two-vial collection kit. This collection kit has been in use for many years. If the fecal specimen arrives in the laboratory in preservative, the direct wet mount for motility should not be performed. The complete ova and parasite examination consists of the concentration and permanent stained smear. PVA, polyvinyl alcohol; SAF, sodium acetate-acetic acid-formalin.



ONE VIAL COLLECTION KIT
(1) SAF
CONCENTRATION
PERMANENT STAINED SMEAR (IRON-HEMATOXYLIN)
HELMINTH EGGS/LARVAE PROTOZOAN CYSTS
PROTOZOAN TROPHOZOITES AND CYSTS
GENERAL MORPHOLOGY (PROTOZOA)
PRECISE MORPHOLOGY (PROTOZOA)

Flowchart A2.4 Procedure for processing sodium acetate-acetic acid-formalin (SAF)-preserved stool for the ova and parasite examination. SAF-preserved stool can be used with the fecal immunoassay kits (fluorescent-antibody assay, enzyme immunoassay, and cartridge formats for *Giardia lamblia* and *Cryptosporidium* spp.; kits for the true pathogen *Entamoeba histolytica* or the *Entamoeba histolytica/E. dispar* group require fresh or frozen stools); modified acid-fast stains for coccidia and modified trichrome stains can also be performed from SAF-preserved stool.



PRESERVED STOOL

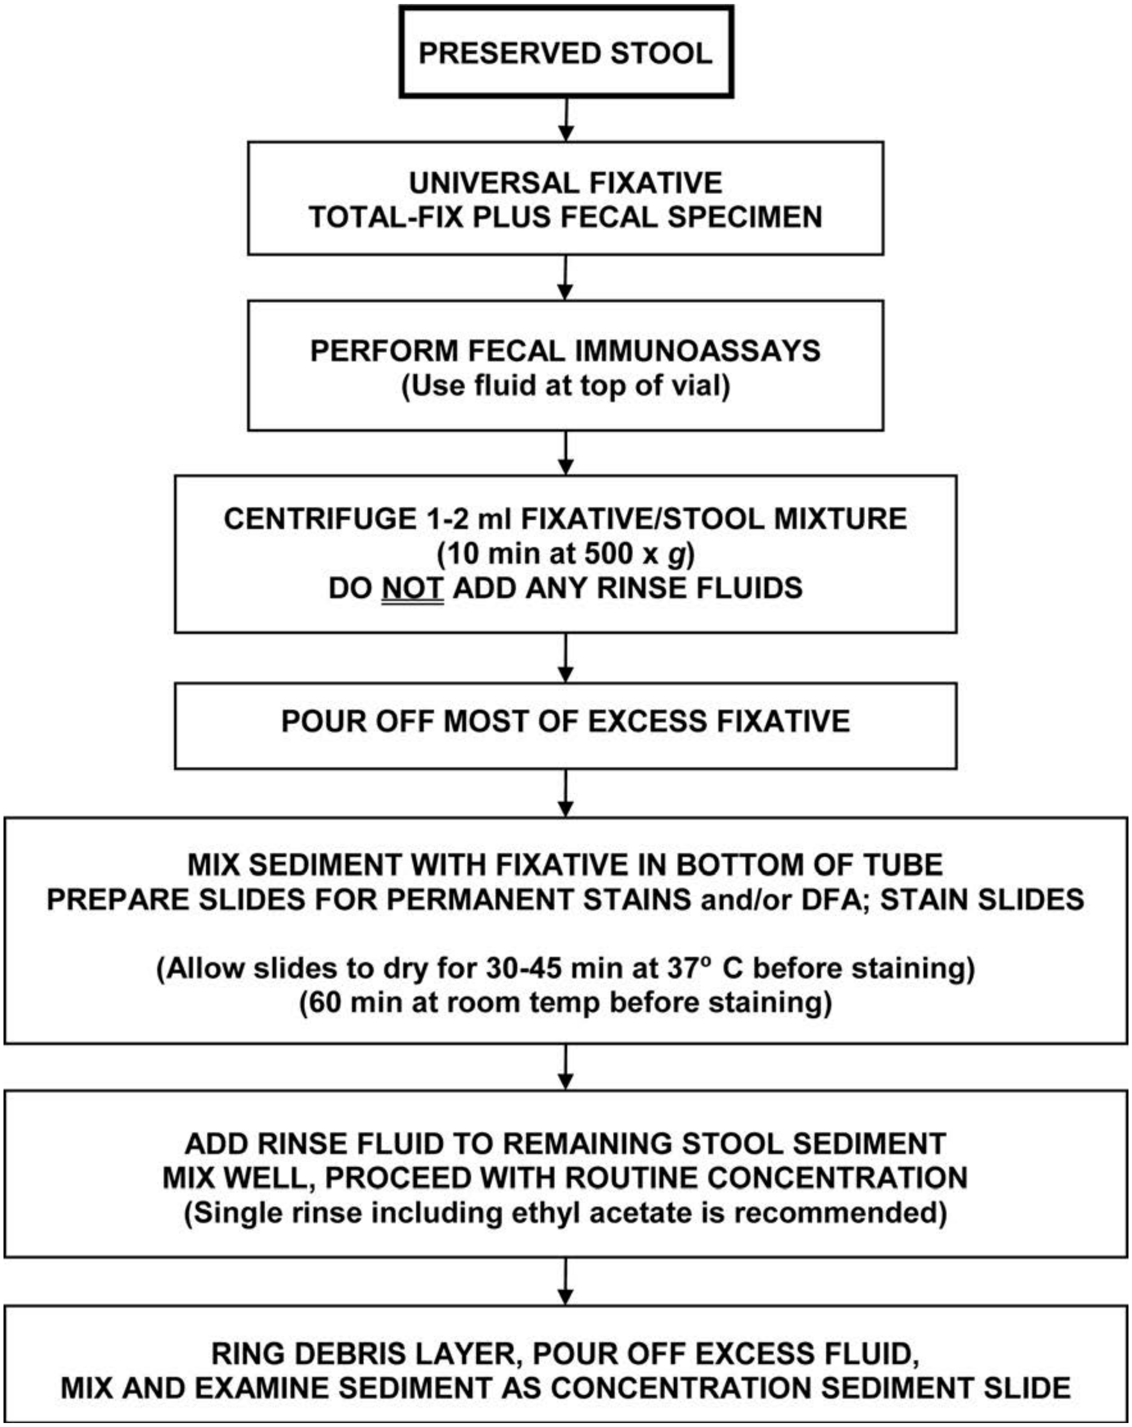
SAF
SINGLE VIAL
SYSTEMS
PVA
(VARIOUS BASES)
SINGLE VIAL SYSTEMS
SAF
MERCURIC CHLORIDE
ZINC SULFATE
COPPER SULFATE
(NOT AS GOOD)
SODIUM ACETATE-
ACETIC ACID-
FORMALIN
STAINS
TRICHROME
IRON HEMATOXYLIN
(CARBOL FUCHSIN STEP)
STAINS
IRON HEMATOXYLIN
(CARBOL FUCHSIN STEP)

Flowchart A2.5 Use of various fixatives and their recommended stains. Fecal specimens preserved using polyvinyl alcohol (PVA) fixative (liquid fixative into which PVA plastic powder has been added) can be stained using either the iron hematoxylin or trichrome stains. However, fecal specimens preserved using sodium acetate-acetic acid-formalin appear to stain better using the iron hematoxylin approach. The single-vial preservatives (proprietary formulas) can be stained with iron hematoxylin, trichrome, or a manufacturer's stain prepared to accompany a particular fixative. *It is important to remember that parasite morphology (particularly intestinal protozoa) may not be as precise or clear as that seen when stool specimens are preserved in Schaudinn's fixative prepared with the mercuric chloride base (gold standard).*



PRESERVED STOOL
UNIVERSAL FIXATIVE
TOTAL-FIX PLUS FECAL SPECIMEN
PERFORM FECAL IMMUNOASSAYS
(Use fluid at top of vial)
CENTRIFUGE 1-2 ml FIXATIVE/STOOL MIXTURE
(10 min at 500 x g)
DO NOT ADD ANY RINSE FLUIDS
POUR OFF MOST OF EXCESS FIXATIVE
MIX SEDIMENT WITH FIXATIVE IN BOTTOM OF TUBE
PREPARE SLIDES FOR PERMANENT STAINS and/or DFA; STAIN SLIDES
(Allow slides to dry for 30-45 min at 37° C before staining)
(60 min at room temp before staining)
ADD RINSE FLUID TO REMAINING STOOL SEDIMENT
MIX WELL, PROCEED WITH ROUTINE CONCENTRATION
(Single rinse including ethyl acetate is recommended)
RING DEBRIS LAYER, POUR OFF EXCESS FLUID,
MIX AND EXAMINE SEDIMENT AS CONCENTRATION SEDIMENT SLIDE

Flowchart A2.6 Use of various fixatives and their recommended stains. Fecal specimens preserved in the Universal Fixative, TOTAL-FIX, can be stained using trichrome or iron hematoxylin. Using this processing algorithm, modified acid-fast stains (coccidia) and modified trichrome stains (microsporidia) can also be performed.

TABLE A2.1 Steps in the trichrome staining procedure (mercuric chloride-based PVA-preserved stool specimens)

Steps in the procedure	Time	Comments
Prepare slide for staining		Can be prepared from Schaudinn's liquid fixative or from mercuric chloride-based polyvinyl alcohol (PVA)
70% ethanol	5 min	Rinses off excess Schaudinn's fixative
70% ethanol + iodine	5 min	Color should look like strong tea; iodine will remove mercury from fecal smears; 10 min may be better if staining a full rack of slides[a]
70% ethanol	5 min	Rinses off excess iodine
70% ethanol	5 min	Completes removal of iodine
Trichrome stain[b]	10 min (variable)	Both mercury and iodine have been removed prior to placing the smears in stain
90% ethanol + acetic acid	Several dips	This begins the destaining process; it is important to move the smears rapidly from this dish to the next so that the destaining does not continue too long
95 or 100% ethanol	Several dips	This step removes the acidified alcohol, preventing the decolorizing step from continuing
100% ethanol	3–5 min	This step begins the dehydration process, in which all moisture is removed from the smear
100% ethanol	3–5 min	Dehydration process continues
Xylene or xylene substitute	5–10 min	Dehydration process continues
Xylene or xylene substitute	5–10 min	Dehydration process completed
Permount slides or allow them to air dry with no coverslip (see Table A2.7)		Permounted slides should be allowed to dry; they can be placed on trays and put in the incubator for 30 min or overnight; room temperature overnight is also sufficient

[a] The iodine-alcohol does not require an exact concentration. The color should not be too dark or the iodine will stain the protozoa, interfering with the subsequent trichrome staining; however, the color should not be too light or the mercuric chloride in the fixative will not be removed and mercuric chloride residue in the stained fecal smear will interfere with examination. Again, a strong-tea color is preferred (do not use "port wine" as a potential color intensity guide; this color is too dark).

[b] The trichrome staining procedure is a "regressive staining method" in which the fecal smears are overstained and then destained to provide better color and contrast.

TABLE A2.2 Steps in the trichrome staining procedure (non-mercuric chloride-based PVA-preserved stool specimens)

Steps in the procedure	Time	Comments
Prepare slide for staining		Can be prepared from non-mercuric chloride-based Schaudinn's fixative, with polyvinyl alcohol (PVA); examples would be Schaudinn's fixative prepared with the zinc sulfate or copper sulfate bases
70% ethanol	5 min	This dish is optional; a rinse can be used for dry smears (PVA) or from liquid Schaudinn's liquid fixative
Trichrome stain[a]	10 min (variable)	Since no mercury is present on the smear, there is no need to use the iodine dish; **however, when staining proficiency testing specimens that have been preserved in mercuric chloride-based fixatives, the iodine dish and subsequent rinse steps must be added back into your staining protocol; some proficiency testing agencies are now using fecal specimens preserved in fixatives containing no mercury; it is important to know what type of fixative was used prior to staining**
90% ethanol + acetic acid	Several dips	This begins the destaining process; it is important to move the smears rapidly from this dish to the next so that the destaining does not continue too long
95 or 100% ethanol	Several dips	This step removes the acidified alcohol, preventing the decolorizing step from continuing
100% ethanol	3–5 min	This step begins the dehydration process, in which all moisture is removed from the smear
100% ethanol	3–5 min	Dehydration process continues
Xylene or xylene substitute	5–10 min	Dehydration process continues
Xylene or xylene substitute	5–10 min	Dehydration process completed
Permount slides or allow them to air dry with no coverslip (see Table A2.7)		Permounted slides should be allowed to dry; they can be placed on trays and put in the incubator for 30 min or overnight; room temperature overnight is also sufficient

[a] The trichrome staining procedure is a "regressive staining method" in which the fecal smears are overstained and then destained to provide better color and contrast.

TABLE A2.3 Steps in the iron hematoxylin staining procedure (mercuric chloride-based PVA-preserved stool specimens) (Spencer-Monroe method)

Steps in the procedure	Time	Comments
Prepare slide for staining		Can be prepared from Schaudinn's liquid fixative or mercuric chloride-based polyvinyl alcohol (PVA); sodium acetate-acetic acid-formalin (SAF)-preserved specimens are also recommended
70% ethanol	5 min	Rinses off excess Schaudinn's fixative
70% ethanol + iodine	5 min	Color should look like strong tea; iodine will remove mercury from fecal smears; 10 min may be better if staining a full rack of slides[a]
70% ethanol (begin the process for SAF-preserved smears or non-mercuric chloride-preserved specimens at this point)	5 min	Rinses off excess iodine
Rinse in running tap water	10 min	Use a constant stream of water running into the container
Place in iron hematoxylin working solution	4–5 min	This step is the staining process
Rinse in running tap water	10 min	Use a constant stream of water running into the container
70% ethanol	5 min	This step begins the dehydration process in which all moisture is removed from the smear
95% ethanol	5 min	Dehydration process continues
100% ethanol	3–5 min	Dehydration process continues
100% ethanol	3–5 min	Dehydration process continues
Xylene or xylene substitute	5–10 min	Dehydration process continues
Xylene or xylene substitute	5–10 min	Dehydration process completed
Permount slides or allow them to air dry with no coverslip (see Table A2.7)		Permounted slides should be allowed to dry; they can be placed on trays and put in the incubator for 30 min or overnight; room temperature overnight is also sufficient

[a] The iodine-alcohol does not require an exact concentration. The color should not be too dark, or the iodine will stain the protozoa, interfering with the subsequent trichrome staining; however, the color should not be too light, or the mercuric chloride in the fixative will not be removed and mercuric chloride residue in the stained fecal smear will interfere with examination. Again, a strong-tea color is preferred (do not use "port wine" as a potential color intensity guide; this color is too dark).

TABLE A2.4 Steps in the iron hematoxylin staining procedure (mercuric chloride-based PVA-preserved stool specimens) (Tompkins-Miller method)

Steps in the procedure	Time	Comments
Prepare slide for staining		Can be prepared from Schaudinn's liquid fixative or mercuric chloride-based polyvinyl alcohol (PVA); sodium acetate-acetic acid-formalin (SAF)-preserved specimens are also recommended
70% ethanol	5 min	Rinses off excess Schaudinn's fixative
70% ethanol + iodine	5 min	Color should look like strong tea; iodine will remove mercury from fecal smears; 10 min may be better if staining a full rack of slides[a]
50% ethanol (begin the process for SAF-preserved smears or non-mercuric chloride-preserved specimens at this point)	5 min	Rinses off excess iodine
Rinse in running tap water	3 min	Use a constant stream of water running into the container
Place in 4% ferric ammonium sulfate mordant	5 min	This prepares the smear to take up the stain
Rinse in running tap water	1 min	Use a constant stream of water running into the container
Place in 0.5% aqueous hematoxylin	2 min	This begins the staining process
Rinse in running tap water	1 min	Use a constant stream of water running into the container
Place in 2% phosphotungstic acid	2–5 min	This provides the destaining process[b]
Rinse in running tap water	10 min	Use a constant stream of water running into the container
70% ethanol + a few drops of saturated aqueous lithium carbonate	3 min	The purpose of this step is to "blue up" the color
95% ethanol	5 min	This step begins the dehydration process in which all moisture is removed from the smear
100% ethanol	3–5 min	Dehydration process continues
100% ethanol	3–5 min	Dehydration process continues
Xylene or xylene substitute	5–10 min	Dehydration process continues
Xylene or xylene substitute	5–10 min	Dehydration process completed
Permount slides or allow them to air dry with no coverslip (see Table A2.7)		Permounted slides should be allowed to dry; they can be placed on trays and put in the incubator for 30 min or overnight; room temperature overnight is also sufficient

---

[a] The iodine-alcohol does not require an exact concentration. The color should not be too dark or the iodine will stain the protozoa, interfering with the subsequent trichrome staining; however, the color should not be too light or the mercuric chloride in the fixative will not be removed and mercuric chloride residue in the stained fecal smear will interfere with examination. Again, a strong-tea color is preferred (do not use "port wine" as a potential color intensity guide; this color is too dark).

[b] Like the trichrome stain, this iron hematoxylin staining procedure is a "regressive staining method" in which the fecal smears are overstained and then destained to provide better color and contrast.

TABLE A2.5 Steps in the iron hematoxylin staining procedure (incorporating the carbol fuchsin step)[a]

Steps in the procedure	Time	Comments
Prepare slide for staining		Can be prepared from SAF-preserved specimens (SAF sediment placed on albumin-coated slides); **specimens preserved in Schaudinn's fixative and/or PVA are not recommended** (**any preservative containing mercuric chloride or PVA powder is not recommended**)
70% ethanol	5 min	Helps "glue" the material onto the slide
Rinse in container of tap water	2 min	Do not use running water
Place in Kinyoun's stain	5 min	Stains for modified acid-fast characteristics
Rinse in running tap water	1 min	Use a constant stream of water running into the container
Acid-alcohol decolorizer (0.5% acid-alcohol)	4 min	This must not be too strong or *Cyclospora cayetanensis* will decolorize too much[b]
Rinse in running tap water	1 min	Use a constant stream of water running into the container
Place in iron hematoxylin working solution	8 min	This begins the staining process
Rinse in container of tap water	1 min	Do not use running water
Place in picric acid solution	3–5 min	This step differentiates the hematoxylin stain
Rinse in running tap water	10 min	Use a constant stream of water running into the container
70% ethanol + some ammonia to bring pH to 8.0	3 min	The purpose of this step is to "blue up" the color
95% ethanol	5 min	This step begins the dehydration process
100% ethanol	3–5 min	Dehydration process continues
100% ethanol	3–5 min	Dehydration process continues
Xylene or xylene substitute	5–10 min	Dehydration process continues
Xylene or xylene substitute	5–10 min	Dehydration process completed
Permount slides or allow them to air dry with no coverslip (see Table A2.7)		Permounted slides should be allowed to dry; they can be placed on trays and put in the incubator for 30 min or overnight; room temperature overnight is also sufficient

---

[a] This staining approach not only stains the intestinal protozoa (iron hematoxylin) but also stains the coccidia (*Cryptosporidium* spp., *Cyclospora cayetanensis*, and *Cystoisospora belli*), which are modified acid-fast positive.

[b] This iron hematoxylin staining procedure is a "regressive staining method" in which the fecal smears are overstained and then destained to provide better color and contrast.

TABLE A2.6 Steps in the trichrome staining procedure (Universal Fixative [no mercury, no formalin, no PVA])

Steps in the procedure	Time	Comments
Preserve stool in fixative	Fix 30 min	Ratio of 1/3 stool, 2/3 fixative, MIX WELL
Perform fecal immunoassays, if requested		Use the fluid at the top if the vial; if vial is shaken, allow to stand so particulate matter will settle out (10 min)
Centrifugation, 10 min @ 500 × *g*	10 min	Add approximately 1–2 ml stool/fixative mix to a tube or device for centrifugation; DO NOT ADD ANY RINSE FLUIDS
Smear preparation		Pour off most of supernatant fluid; mix sediment with remaining fixative; prepare fecal smears for permanent staining (trichrome), special stains for coccidia or microsporidia, or DFA immnoassay
Concentration*		**SEE LAST TWO STEPS BELOW**
Smear drying time	30–45 min at 37°C, 60 min at room temp	This step ensures the smears are thoroughly dry prior to staining
70% ethanol	5 min	This dish is optional; a rinse can be used for dry smears
Trichrome stain[a]	10 min (variable)	Since no mercury is present on the smear, there is no need to use the iodine dish; **however, when staining proficiency testing specimens that have been preserved in mercuric chloride-based fixatives, the iodine dish and subsequent rinse steps must be added back into your staining protocol; some proficiency testing agencies are now using fecal specimens preserved in fixatives containing no mercury; it is important to know what type of fixative was used prior to staining**
90% ethanol + acetic acid	Several dips	This begins the destaining process; it is important to move the smears rapidly from this dish to the next so that the destaining does not continue too long
100% ethanol	Several dips	This step removes the acidified alcohol, preventing the decolorizing step from continuing
100% ethanol	3–5 min	This step begins the dehydration process, in which all moisture is removed from the smear
Xylene or xylene substitute	5–10 min	Dehydration process continues
Xylene or xylene substitute	5–10 min	Dehydration process completed
Permount slides or allow them to air dry with no coverslip (see Table A2.7)		Permounted slides should be allowed to dry; they can be placed on trays and put in the incubator for 30 min or overnight; room temperature overnight is also sufficient
Concentration*	10 min	Add rinse fluid to remainder of stool sediment and proceed with the routine concentration (500 × *g* for 10 min) Single rinse plus ethyl acetate step is recommended
Prepare concentration for examination*	2 min	Ring debris layer, pour off excess fluid, mix, and examine sediment as concentration sediment slide

[a] The trichrome staining procedure is a "regressive staining method" in which the fecal smears are overstained and then destained to provide better color and contrast.

TABLE A2.7 Oil-mounted permanent stained smears (no Permount is used)

Steps in the procedure	Time	Comments
Remove stained smears from last dehydration step (xylene or xylene substitute) and place them flat on paper towels to dry	Allow to dry for 10 min	If using a xylene substitute, the smears will take longer to dry; leave on paper towels for 15–20 min
Once the fecal smears are dry, place 1 to 2 drops of immersion oil onto the dry fecal smear	3–5 min	Allow the oil to "sink into" the dry fecal smear; if the smears are somewhat thick, wait 10–15 min before microscopic examination
Place a no. 1 coverslip onto the fecal smear/oil combination	No waiting time required	A 22- by 22-mm coverslip is recommended; the addition of the coverslip will prevent damage to the oil lens when microscopic examination begins; when fecal material on the smear has been thoroughly dehydrated, the material may be hard/brittle and could scratch the oil lens if not protected
Add 1 drop of immersion oil to the top of the coverslip[a]	No waiting time required	The fecal smear is now ready to examine using the oil immersion objective (100× lens for a total magnification of ×1,000)

[a] The layers are as follows: glass slide, fecal smear, immersion oil, coverslip, immersion oil; this approach works quite well and is a substitute for the use of Permount or other mounting fluids. If a positive smear is found, the oil can be removed in xylene or xylene substitute and mounted with Permount and a coverslip in the normal way. The negative slides can be stored in a slide box that is recycled every month or so, and the old slides can then be discarded.

TABLE A2.8 Tips on stool processing and staining

Processing or staining step	Commentary and tips
Direct wet mount, water or saline	In general, organisms do not like distilled water; even in saline, trophozoites may not maintain adequate morphology very long; even with viable organisms, motility may be difficult to see (lower microscope light intensity); direct wet mounts should be prepared on liquid or very soft stools only (more formed stools usually do not contain any trophozoites)
Direct wet mount, iodine	If the iodine is too dark, it may interfere with helminth egg detection; eggs resemble debris and/or artifacts; internal protozoan morphology may be too dark; iodine should be the color of strong tea; iodine kills the organisms, so that no motility will be seen
Concentration-sedimentation	Rinse solutions can be water, saline, or formalin (regular 5% or 10% solution); do not rinse too many times (the supernatant fluid does *not* have to be clear); although a cleaner sediment may be easier to read, too much rinsing results in loss of organisms; a dirtier sediment is preferred to maximize organism detection; do not make coverslip preparations too thick (thinner is preferable); every centrifugation step should be at 500 × *g* for 10 min
Concentration-flotation	Rinse solutions can be water, saline, or formalin (regular 5% or 10% solution); do not rinse too many times (the supernatant fluid does *not* have to be clear); the more you rinse, the more likely you are to lose organisms each time; many labs use a single rinse or two at the most; it is important to use zinc sulfate of the correct specific gravity (1.18 for non-formalin-fixed material, 1.20 for specimens received in formalin); ***both*** **the surface film and sediment must be examined (not all parasites float in the zinc sulfate method)**
Permanent stained smear: smear preparation	The smear should be neither too thick nor too thin (you should be able to read newsprint through the fecal smear); if using polyvinyl alcohol (PVA)-preserved specimens, make sure that the excess PVA is removed from the stool prior to smear preparation (absorb excess PVA from specimen by placing a bit of specimen onto paper towels, wait a few minutes, and then prepare smears); smears should be thoroughly dry prior to staining (with the exception of using liquid Schaudinn's fixative); **formalin-fixed stool is not appropriate for permanent staining**
Permanent stained smear: staining	If specimen is preserved in a fixative containing mercuric chloride, it is mandatory that all mercury be removed prior to staining (iodine and subsequent alcohol steps); dehydration (moisture removal) must be complete or protozoan morphology will be difficult to see; the best dehydration is obtained with absolute ethanol; if the "commercial" absolute alcohol is used (ethanol plus other alcohols), the dehydration is not as complete, so dishes containing this solution must be changed more often (at least weekly and every few days if staining more than a few slides at a time); xylene substitutes do not dehydrate as well as xylene (dishes must be changed more often); xylene substitutes take longer to dry; however, slides must be thoroughly dry prior to mounting with immersion oil (see Table A2.7); **formalin-fixed stool is not appropriate for permanent staining**
Permanent stained smear: specimen preparation and staining (Universal Fixative)	See Appendix 2.6 for complete protocol using the Universal Fixative (incorporates guidelines for fecal immunoassays, concentration, routine permanent stained smear [e.g., trichrome], and special stains for coccidia [modified acid fast] and microsporidia [modified trichrome])

APPENDIX 3

Common Problems in Parasite Identification

The drawings (except Figure A3.27) are reprinted from Isenberg HD (ed), *Clinical Microbiology Procedures Handbook*, 2nd ed, ASM Press, Washington, DC, 2004. Other confusing artifacts can be seen in chapter 34.

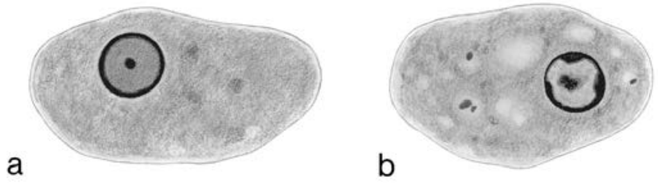


Figure A3.1 (a) *Entamoeba histolytica*/*E. dispar* trophozoite. Note the evenly arranged nuclear chromatin, central compact karyosome, and relatively clean cytoplasm. (b) *Entamoeba coli* trophozoite. Note the unevenly arranged nuclear chromatin, eccentric karyosome, and messy cytoplasm. These characteristics are very representative of the two organisms. However, in actual clinical specimens, there is great overlap between morphologic characteristics. When examining a patient specimen with a suspected mixed infection, one looks for two populations of organisms. When the majority of organisms seen appear to be from one genus/species, a rare one or two unusual organisms may just be outliers of the same genus/species that look a bit different. (Illustration by Sharon Belkin.)

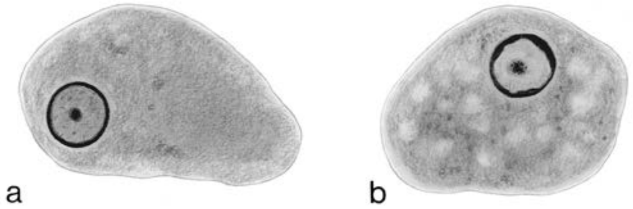

Figure A3.2 (a) *Entamoeba histolytica*/*E. dispar* trophozoite. Note the evenly arranged nuclear chromatin, central compact karyosome, and clean cytoplasm. (b) *Entamoeba coli* trophozoite. Note that the nuclear chromatin appears to be evenly arranged, the karyosome is central (but more diffuse), and the cytoplasm is messy, with numerous vacuoles and ingested debris. The nuclei of these two organisms tend to resemble one another (a very common finding in routine clinical specimens). However, the karyosome in *E. coli* tends to be larger and more blot-like. (Illustration by Sharon Belkin.)

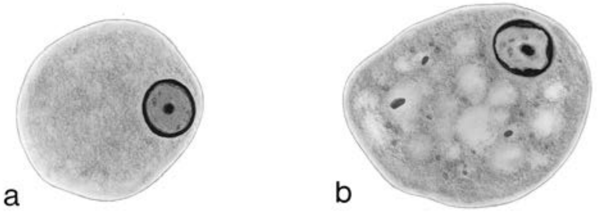

Figure A3.3 (a) *Entamoeba histolytica*/*E. dispar* trophozoite. Again, note the typical morphology (evenly arranged nuclear chromatin, central compact karyosome, and relatively clean cytoplasm). (b) *Entamoeba coli* trophozoite. Although the nuclear chromatin is eccentric, note that the karyosome seems to be compact and central. However, note the various vacuoles containing ingested debris. These organisms show some characteristics that are very similar (very common in clinical specimens). The nature of the karyosome tends to be very helpful; in *E. histolytica*/*E. dispar* the karyosome tends to be compact (may or may not be in the center). The karyosome of *E. coli* tends to be larger, more diffuse, and more irregular; it may or may not be eccentric. (Illustration by Sharon Belkin.)

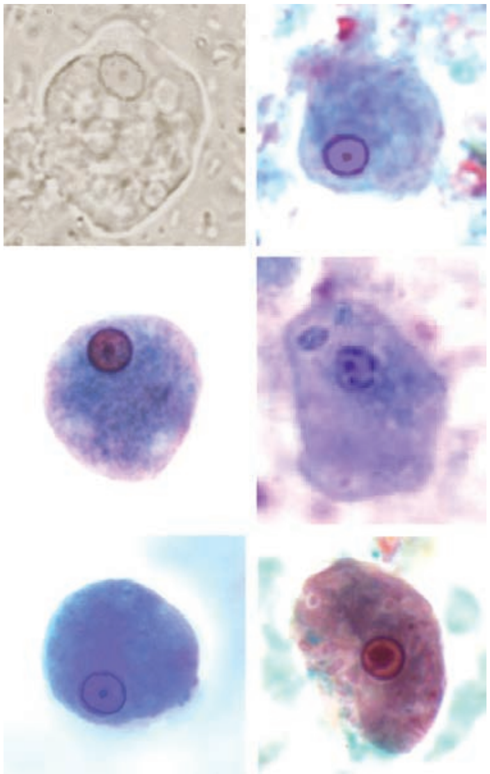

Figure A3.4 (Top) *Entamoeba histolytica*/*E. dispar* trophozoites shown in a wet preparation (left) and a permanent stained smear (right). (Middle) *E. histolytica*/*E. dispar* trophozoite in permanent stained smear (left); *Entamoeba coli* trophozoite in permanent stained smear (right). (Bottom) *E. histolytica*/*E. dispar* trophozoite in permanent stained smear (left); *E. coli* trophozoite in permanent stained smear (right). Note the differences in the nucleus and cytoplasm: *E. histolytica*/*E. dispar* has even nuclear chromatin, a central, compact karyosome, and clean cytoplasm, whereas *E. coli* has uneven nuclear chromatin, eccentric karyosome, and messy/dirty cytoplasm. However, often there are nuclear and cytoplasmic characteristics that are not specific for one species or another; too many characteristics are seen that resemble either or both species. Again, the important differences can be seen as two populations of organisms. It may be difficult to assign a species designation to every organism seen, while the overall set of characteristics generally allow the organisms to be assigned to one or more species. All images stained with Wheatley's trichrome stain (routine trichrome for fecal specimens).

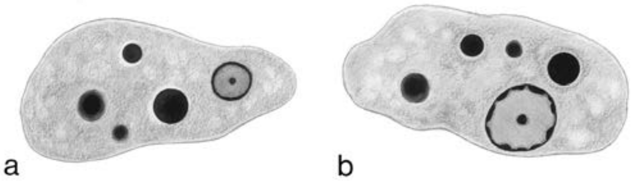

Figure A3.5 (a) *Entamoeba histolytica* trophozoite. Note the evenly arranged nuclear chromatin, central compact karyosome, and red blood cells (RBCs) in the cytoplasm. (b) Human macrophage. The key difference between the macrophage nucleus and that of *E. histolytica* is the size. Usually the ratio of nucleus to cytoplasm in a macrophage is approximately 1:6 or 1:8, while the true organism has a nucleus-to-cytoplasm ratio of approximately 1:10 or 1:12. The macrophage also contains ingested RBCs. In patients with diarrhea or dysentery, trophozoites of *E. histolytica* and macrophages are often confused, occasionally leading to a false-positive diagnosis of amebiasis when no parasites are present. Both the actual trophozoite and the macrophage may also be seen without ingested RBCs and can mimic one another. (Illustration by Sharon Belkin.)

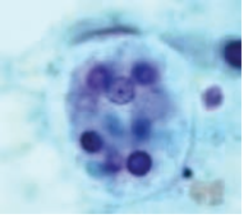
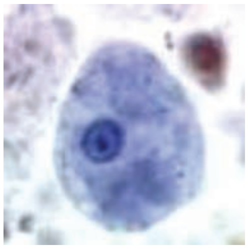
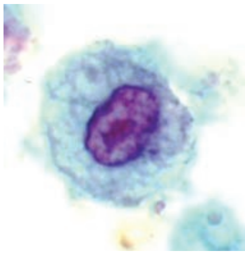
TABLE A3.1 *Entamoeba* spp. trophozoites versus macrophages

Characteristic	***Entamoeba histolytica***	***E. dispar, E. moshkovskii, E. bangladeshi***	**Macrophage**
Size	12–25 µm	12–25 µm	Comparable to protozoa
Red blood cells (RBCs)	Round within vacuoles or may not be present	No RBCs	No RBCs
Nuclear/cytoplasmic ratio	1/10–1/12	1/10–1/12	1/6–1/8
			







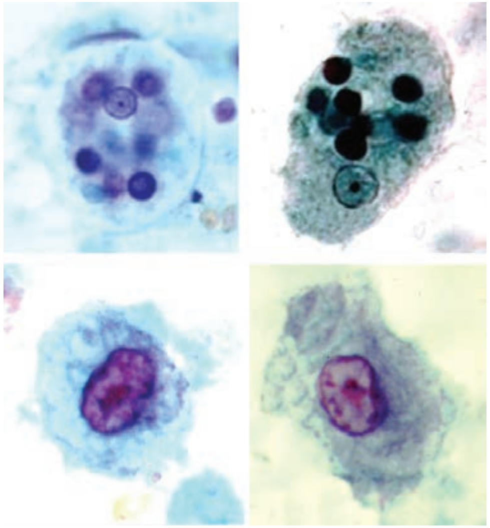


Figure A3.6 (Upper) *Entamoeba histolytica* trophozoites on permanent stained smears; note the evenly arranged nuclear chromatin, central, compact karyosome, and ingested RBCs. The presence of the ingested RBCs indicates the presence of the true pathogen, *E. histolytica*. Without the presence of ingested RBCs, the organism would have been identified as *E. histolytica*/*E. dispar* (it is impossible to determine pathogenicity from the morphology on the permanent stained smear). (Lower) Two macrophages from human fecal specimen. The main difference between the macrophage nucleus and that of *E. histolytica* is the size. Usually the ratio of nucleus to cytoplasm in a macrophage is approximately 1:6 or 1:8, while the true organism has a nucleus-to-cytoplasm ratio of approximately 1:10 or 1:12. All images but one stained with Wheatley's trichrome stain (routine trichrome for fecal specimens); upper right stained with iron-hematoxylin.

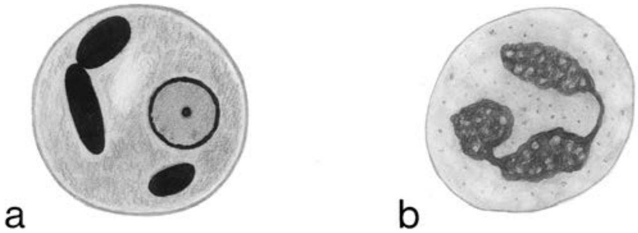

Figure A3.7 (a) *Entamoeba histolytica*/*E. dispar* precyst. Note the enlarged nucleus (prior to division) with evenly arranged nuclear chromatin and central compact karyosome. Chromatoidal bars (rounded ends with smooth edges) are also present in the cytoplasm. (b) Polymorphonuclear leukocyte (PMN). The nucleus is somewhat lobed (normal morphology) and represents a PMN that has not been in the gut very long. Occasionally, the positioning of the chromatoidal bars and the lobed nucleus of the PMN will mimic one another. The chromatoidal bars stain more intensely, but the shapes can overlap, as seen here. (Illustration by Sharon Belkin.)

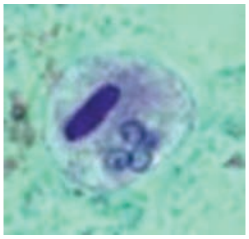
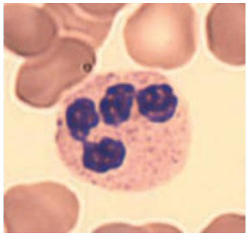
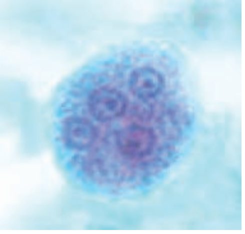
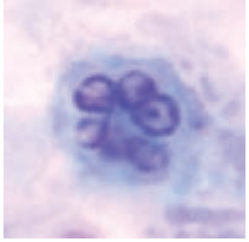
TABLE A3.2 *Entamoeba* spp. cysts versus polymorphonuclear leukocytes (PMNs)

Characteristic	*E. histolytica, E. dispar, E. moshkovskii, E. bangladeshi*	PMNs
Size	10–15 µm	10–15 µm
RBCs	Not present	Not present
No. of nuclei	4	4–5, may be lobed (2–5 nuclear lobes)
Shape of nuclei	Usually round and consistent shape	Irregular shapes and may vary tremendously
				









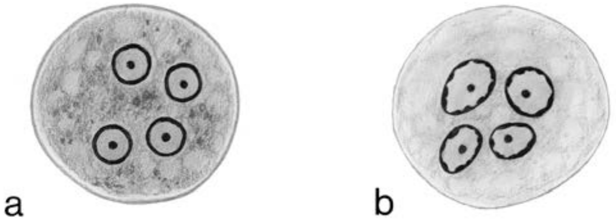


Figure A3.8 (a) *Entamoeba histolytica/E. dispar* mature cyst. Note that the four nuclei are very consistent in size and shape. (b) PMN. Note that the normal lobed nucleus has now broken into four fragments, which mimic four nuclei with peripheral chromatin and central karyosomes. When PMNs have been in the gut for some time and have begun to disintegrate, the nuclear morphology can mimic that seen in an *E. histolytica/E. dispar* cyst. However, human cells are often seen in the stool in patients with diarrhea; with rapid passage of the gastrointestinal tract contents, there will not be time for amebic cysts to form. Therefore, for patients with diarrhea and/or dysentery, if "organisms" that resemble the cell in panel b are seen, think first of PMNs, not *E. histolytica/E. dispar* cysts. (Illustration by Sharon Belkin.)

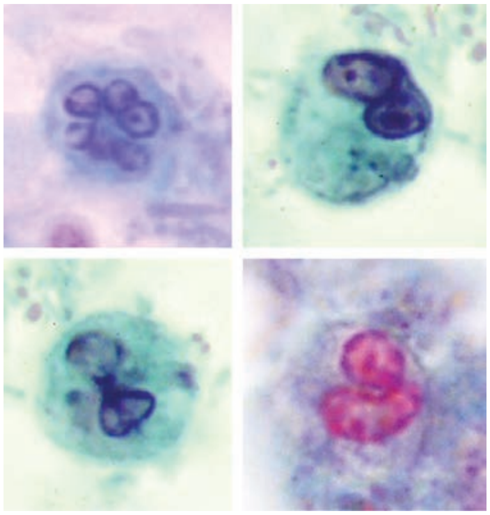
Figure A3.9 (Upper) PMNs. Note the appearance of "multiple nuclei" in the cell on the left, while the cell on the right contains the lobed nucleus, which has not yet fragmented to mimic an *Entamoeba* cyst. (Lower) PMNs in which the lobed nuclei have not yet fragmented; these cells should not be confused with *Entamoeba* cysts. When PMNs have been in the gut for some time and have begun to disintegrate, the nuclear morphology can mimic that seen in an *Entamoeba* cyst. However, remember that in patients with diarrhea, the gut contents move too rapidly for cysts to form; thus, cells with what appear to be multiple nuclei are actually PMNs.



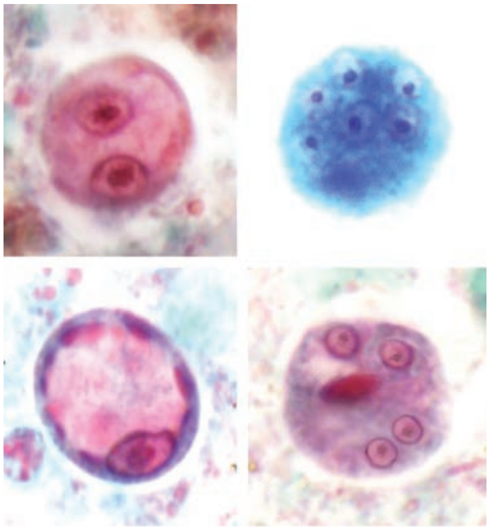


Figure A3.10 (Upper) *Entamoeba coli* precyst with two enlarged nuclei, one on each side of the precyst) (left) and *E. coli* cyst (five or more nuclei) (right). These cells could be confused with PMNs. (Lower) *Entamoeba histolytica/E. dispar* precyst on the left with a single enlarged nucleus; *E. histolytica/E. dispar* mature cyst (containing four nuclei and one chromatoidal bar) on the right. All images stained with Wheatley's trichrome stain (routine trichrome for fecal specimens).

TABLE A3.3 *Entamoeba histolytica* versus *Entamoeba coli* precysts and cysts

Characteristic	*E. histolytica, E. dispar, E. moshkovskii, E. bangladeshi*	*E. coli*
Size	10–15 μm	10–15 μm
RBCs	Not present	Not present
Precyst, no. of nuclei	1	2, one at each side
Precyst, shape of nuclei	Usually round	Often elongated
Precysts		Precysts		Cyst, no. of nuclei	4; some may not be in plane of focus	5 or more; some may not be in plane of focus
Cysts: chromatoidal bars	Chromatoidal bars have smooth, rounded ends	Chromatoidal bars have sharp, spiked edges
		Cysts: chromatoidal bars may not always be visible		

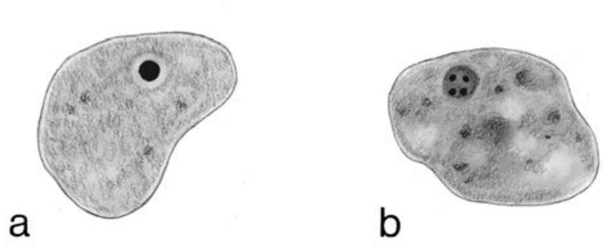

Figure A3.11 (a) *Endolimax nana* trophozoite. This organism is characterized by a large karyosome with no peripheral chromatin, although many nuclear variations are normally seen in any positive specimen. (b) *Dientamoeba fragilis* trophozoite. Normally, the nuclear chromatin is fragmented into several dots (often a "tetrad" arrangement). The cytoplasm is normally more "junky" than that seen in *E. nana*. If the morphology is typical, as in these two illustrations, differentiating between these two organisms is not very difficult. However, the morphologies of the two are often very similar. (Illustration by Sharon Belkin.)

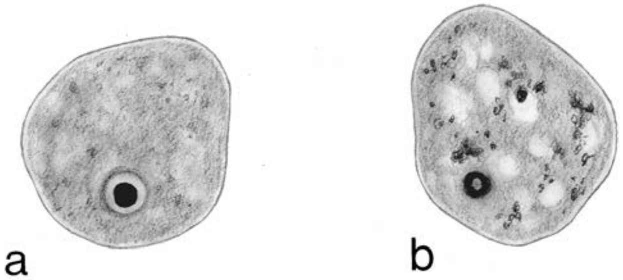

Figure A3.12 (a) *Endolimax nana* trophozoite. Note that the karyosome is large and surrounded by a "halo," with very little chromatin on the nuclear membrane. (b) *Dientamoeba fragilis* trophozoite. In this organism, the karyosome is beginning to fragment and there is a slight clearing in the center of the nuclear chromatin. If the nuclear chromatin has not become fragmented, *D. fragilis* trophozoites can very easily mimic *E. nana* trophozoites. This could lead to a report indicating that no pathogens were present when, in fact, *D. fragilis* is now considered a definite cause of symptoms. (Illustration by Sharon Belkin.)

TABLE A3.4 *Endolimax nana* versus *Dientamoeba fragilis*

Characteristic	***Endolimax nana***	***Dientamoeba fragilis***	**Comments**
Size, trophozoite	6–12 µm	5–15 µm	Both have wide size and shape range
No. of nuclei	1; tremendous nuclear variation in trophozoites	1 or 2; chromatin often fragmented; 1 nucleus	Large overlap in morphology; 2 nuclei
Trophozoites			Size, cyst	5–10 µm	5–10 µm	
Cysts			If a single nucleus only, may be very difficult to differentiate the two organisms; *D. fragilis* is as common as *Giardia*.

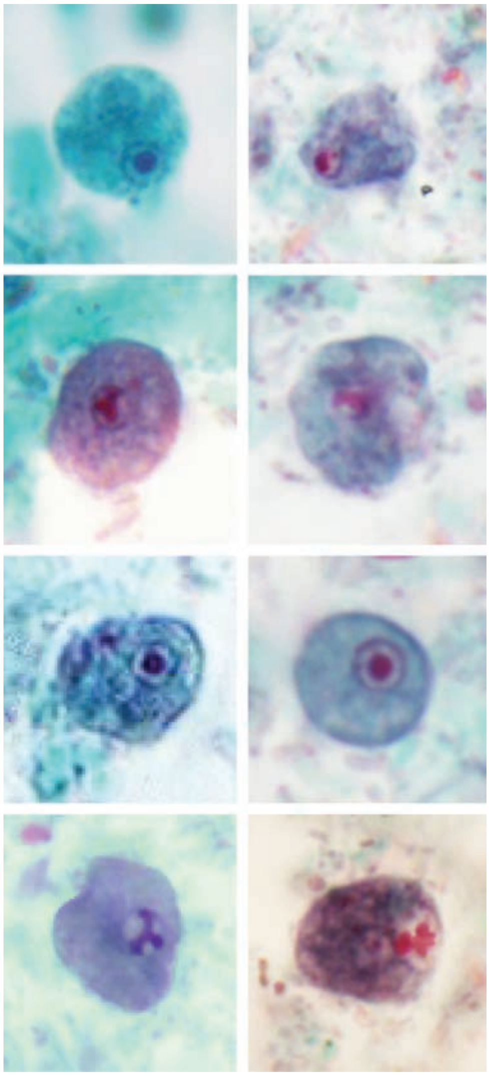

Figure A3.13 *Endolimax nana* trophozoites. Note the tremendous nuclear variation; there is more nuclear variation in this organism than any of the other intestinal protozoa. The karyosome appears quite different from organism to organism; they can mimic *Dientamoeba fragilis* and/or *Entamoeba hartmanni* (particularly if the nucleus appears to have peripheral chromatin like the organisms in row 3 from the top).

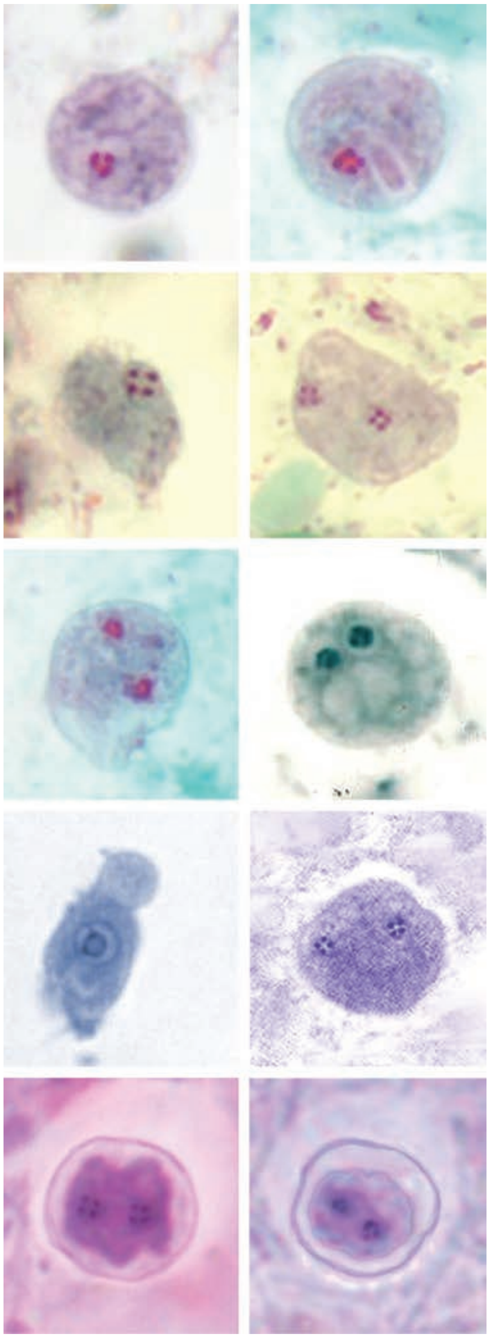

Figure A3.14 *Dientamoeba fragilis* trophozoites. (Top three rows) Some have a single nucleus, while others have two nuclei; the nuclei tend to fragment into several chromatin dots. (Row 4) The image on the left shows the clearing within the karyosome prior to fragmentation into chromatin dots. Both images in this row are stained using iron-hematoxylin. All other images are stained using the Wheatley's routine trichrome stain. (Bottom) These two images show the newly discovered cyst stage, with the double cyst wall (Stark D et al, *J Clin Microbiol* **52**:2680, 2014). However, the cystic forms tend to be rare in human specimens, a probable factor in the original failure to report and confirm these forms.

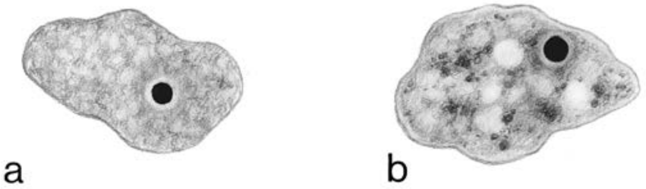

Figure A3.15 (a) *Endolimax nana* trophozoite. Note the large karyosome surrounded by a clear space. The cytoplasm is relatively clean. (b) *Iodamoeba bütschlii* trophozoite. Although the karyosome is similar to that of *E. nana*, note that the cytoplasm in *I. bütschlii* is much more heavily vacuolated and contains ingested debris. Often, these two trophozoites cannot be differentiated. However, the differences in the cytoplasm are often helpful. There is a definite size overlap between the two genera. (Illustration by Sharon Belkin.)

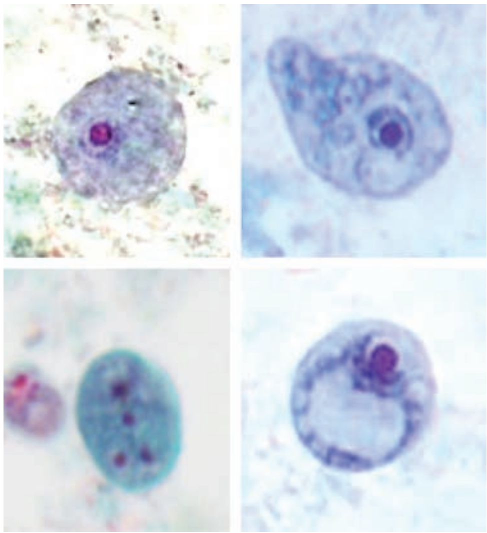

Figure A3.16 (Upper left) *Endolimax nana* trophozoite (note the large single karyosome with very little peripheral chromatin); (right) *Iodamoeba bütschlii* trophozoite (note the large karyosome, some light peripheral nuclear chromatin, and the messy/dirty cytoplasm containing many vacuoles). (Lower left) *E. nana* cyst (note the four karyosomes with no peripheral chromatin; shape tends to be somewhat round to oval); (right) *I. bütschlii* cyst (note the large vacuole, single nucleus with large karyosome, and chromatin granules at one edge of the nucleus [basket nucleus]).

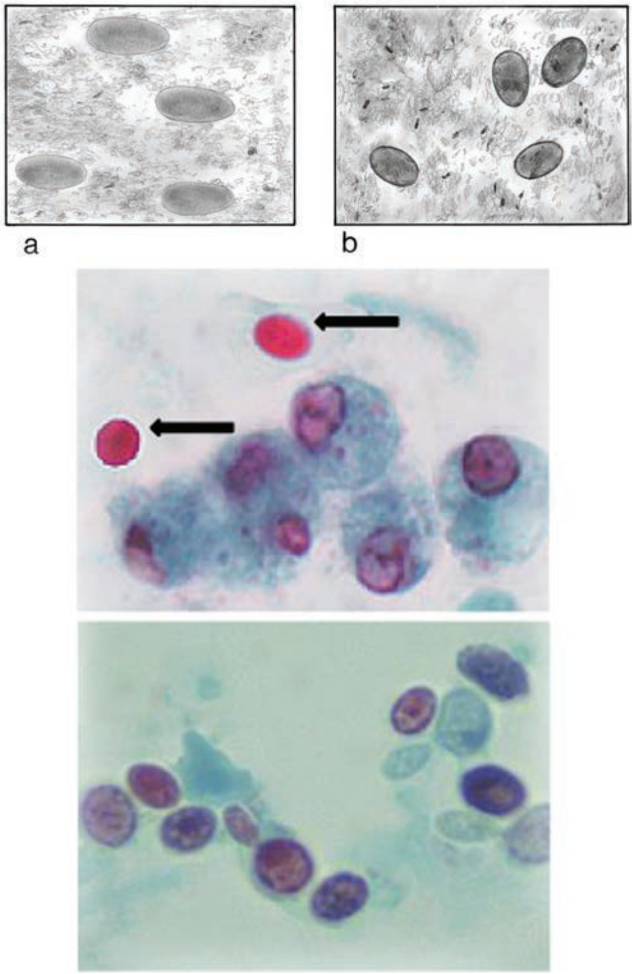

Figure A3.17 (Top) (a) RBCs on a stained fecal smear. Note that the cells are very pleomorphic but tend to be positioned in the direction in which the stool was spread onto the slide. (b) Yeast cells on a stained fecal smear. These cells tend to remain oval and are not aligned in any particular way on the smear. These differences are important when the differential identification is between *Entamoeba histolytica* containing RBCs and *Entamoeba coli* containing ingested yeast cells. If RBCs or yeast cells are identified in the cytoplasm of an organism, they must also be visible in the background of the stained fecal smear. (Illustration by Sharon Belkin.) (Middle) PMNs and RBCs (see arrows). The RBC cell shape can vary tremendously. (Bottom) Yeast cells in fecal material. Note the shape tends to be consistent and there appears to be no particular direction of placement such as is seen frequently with RBCs.

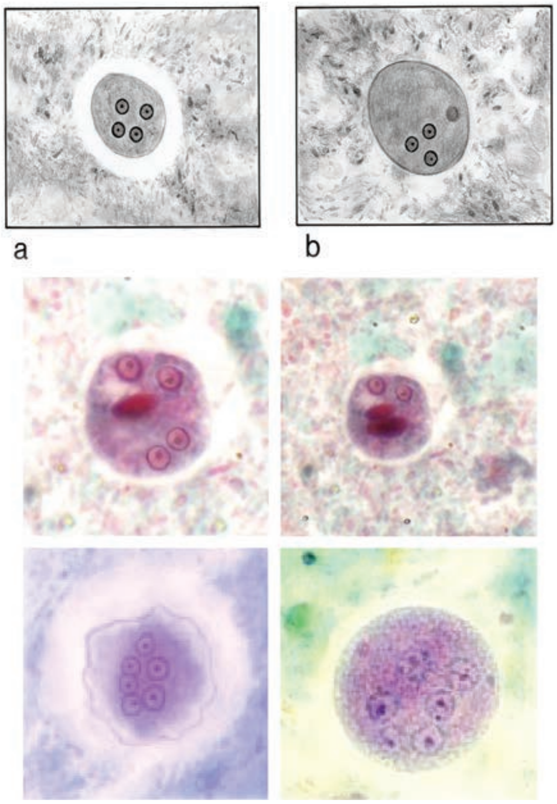

Figure A3.18 (Top) (a) *Entamoeba histolytica/E. dispar* cyst. Note the shrinkage due to dehydrating agents in the staining process. (b) *E. histolytica/E. dispar* cyst. In this case, the cyst exhibits no shrinkage. Only three of the four nuclei are in focus. Normally, this type of shrinkage is seen with protozoan cysts and is particularly important when a species is measured and identified as either *E. histolytica/E. dispar* or *Entamoeba hartmanni*. The whole area, including the halo, must be measured prior to species identification. If just the cyst is measured, the organism would be identified as *E. hartmanni* (nonpathogenic) rather than *E. histolytica/E. dispar* (possibly pathogenic). (Illustration by Sharon Belkin.) (Middle, left) *E. histolytica/E. dispar* cyst with four nuclei and one chromatoidal bar (note the shrinkage around the cyst); (right) *Entamoeba hartmanni* cyst with two of the four nuclei visible and two chromatoidal bars. (Note also the shrinkage around the cyst wall; this entire area would need to be measured for accurate species identification.) (Bottom) *Entamoeba coli* cysts. Note the shrinkage around the cyst wall; however, the identification to species could be made on the basis of five or more visible nuclei.

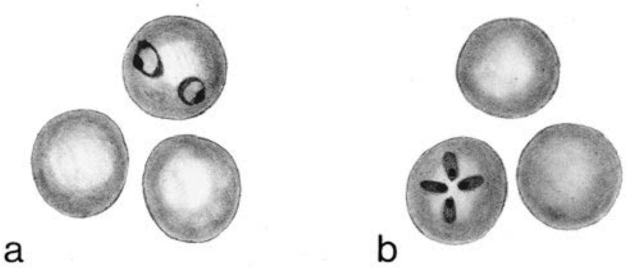

Figure A3.19 (a) *Plasmodium falciparum* rings. Note the two rings in the RBC. Multiple rings per cell are more typical of *P. falciparum* than of the other species causing human malaria. (b) *Babesia* rings. One of the RBCs contains four small *Babesia* rings. This particular arrangement is called the Maltese cross and is diagnostic for *Babesia* spp. (although this configuration is not always seen). *Babesia* infections can be confused with cases of *P. falciparum* malaria, primarily because multiple rings can be seen in the RBCs. Another difference involves ring morphology. *Babesia* rings are often of various sizes and tend to be very pleomorphic, while those of *P. falciparum* tend to be more consistent in size and shape. (Illustration by Sharon Belkin.)

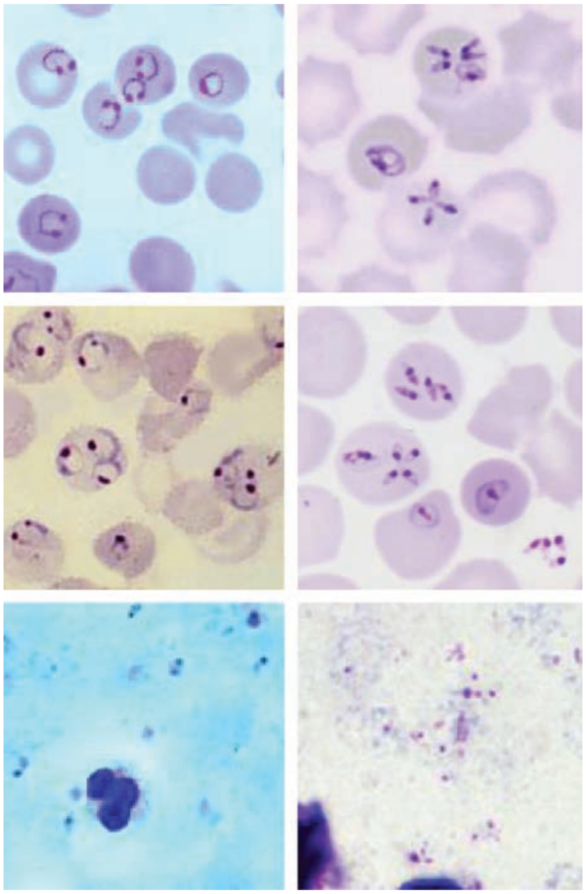

Figure A3.20 (Top, left) *Plasmodium falciparum* rings. Note the "clean" morphology and headphone appearance of some of the rings; (right) *Babesia* spp. Note the "messy/pleomorphic" rings and the presence of the Maltese cross configuration of four rings within a single RBC; this does not occur in every species of *Babesia*. (Middle, left) *P. falciparum* ring forms in a heavy infection (note the clearly defined rings); (right) *Babesia* spp.; note smaller rings. Also note the rings outside of the RBCs, which does not occur in malarial infections. (Bottom, left) *P. falciparum* rings in a thick film (note the nuclei and cytoplasm portion of the ring forms); (right) *Babesia* spp. thick film; note the nuclei are seen and the nuclei appear smaller than those seen in the malaria thick film. However, differentiation of organisms based on thick film morphology can be quite difficult. Identification is best achieved from the thin blood film.

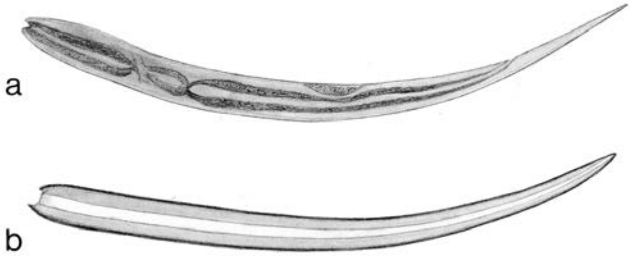

Figure A3.21 (a) *Strongyloides stercoralis* rhabditiform larva. Note the short buccal capsule (mouth opening) and the internal structure, including the genital primordial packet of cells. (b) Root hair (plant material). Note that there is no specific internal structure and the end is ragged where it was broken off from the main plant. Plant material often mimics some of the human parasites. This comparison is one of the best examples. These artifacts are occasionally submitted as proficiency-testing specimens. (Illustration by Sharon Belkin.)

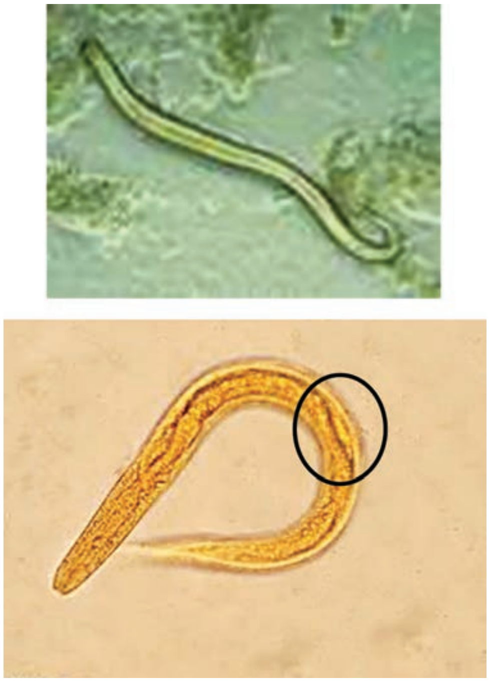

Figure A3.22 (Upper) Root hair artifact that resembles actual nematode larva. (Lower) *Strongyloides stercoralis* rhabditiform larva. Note the internal structures, especially the large, genital primordium packet of cells (circle).

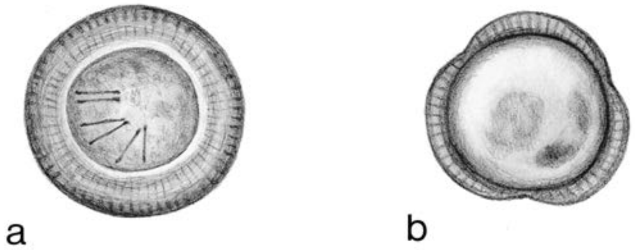

Figure A3.23 (a) *Taenia* egg. This egg has been described as having a thick, radially striated shell containing a six-hooked embryo (oncosphere). (b) Pollen grain. Note that this trilobed pollen grain has a similar type of "shell" and, if turned the right way, could resemble a *Taenia* egg. This similarity represents another source of confusion between a helminth egg and a plant material artifact. When examining fecal specimens in a wet preparation, you can tap on the coverslip to get objects to move around. As they move, you can see more morphologic detail. (Illustration by Sharon Belkin.)

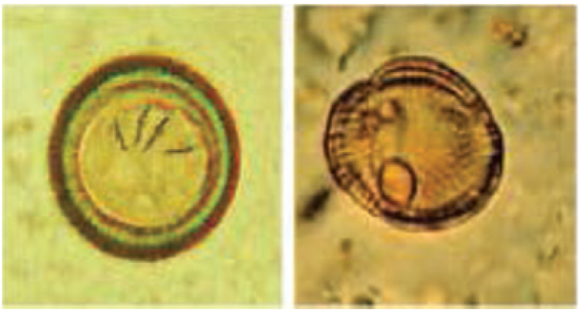

Figure A3.24 (Left) *Taenia* egg, showing the striated shell and six-hooked embryo (oncosphere) within the egg shell. (Right) Pollen grain that can resemble an actual *Taenia* egg. Note that the shape may vary, especially depending on the way the pollen grain is lying in the wet preparation.

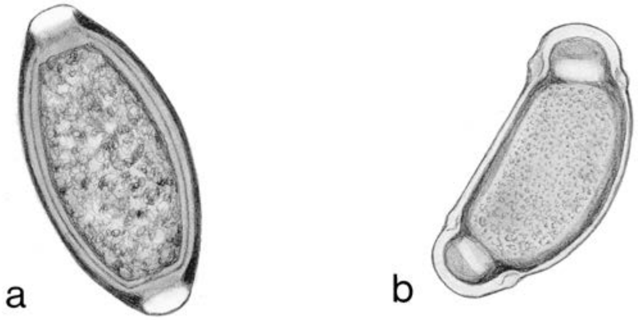

Figure A3.25 (a) *Trichuris trichiura* egg. This egg is typical and is characterized by the barrel shape with thick shell and two polar plugs. (b) Bee pollen. This artifact certainly mimics the *T. trichiura* egg. However, note that the shape is somewhat distorted. This is an excellent example of a parasite look-alike that could be confusing. (Illustration by Sharon Belkin.)

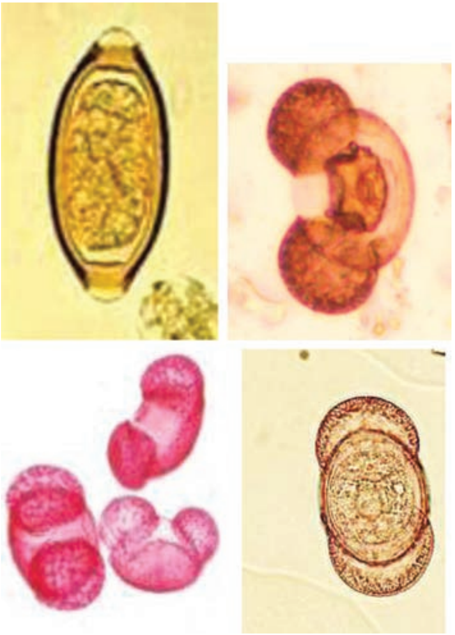

Figure A3.26 (Upper, left) *Trichuris trichiura* egg; (right) pollen that can mimic a *T. trichiura* egg. (Lower) Examples of pine pollen.

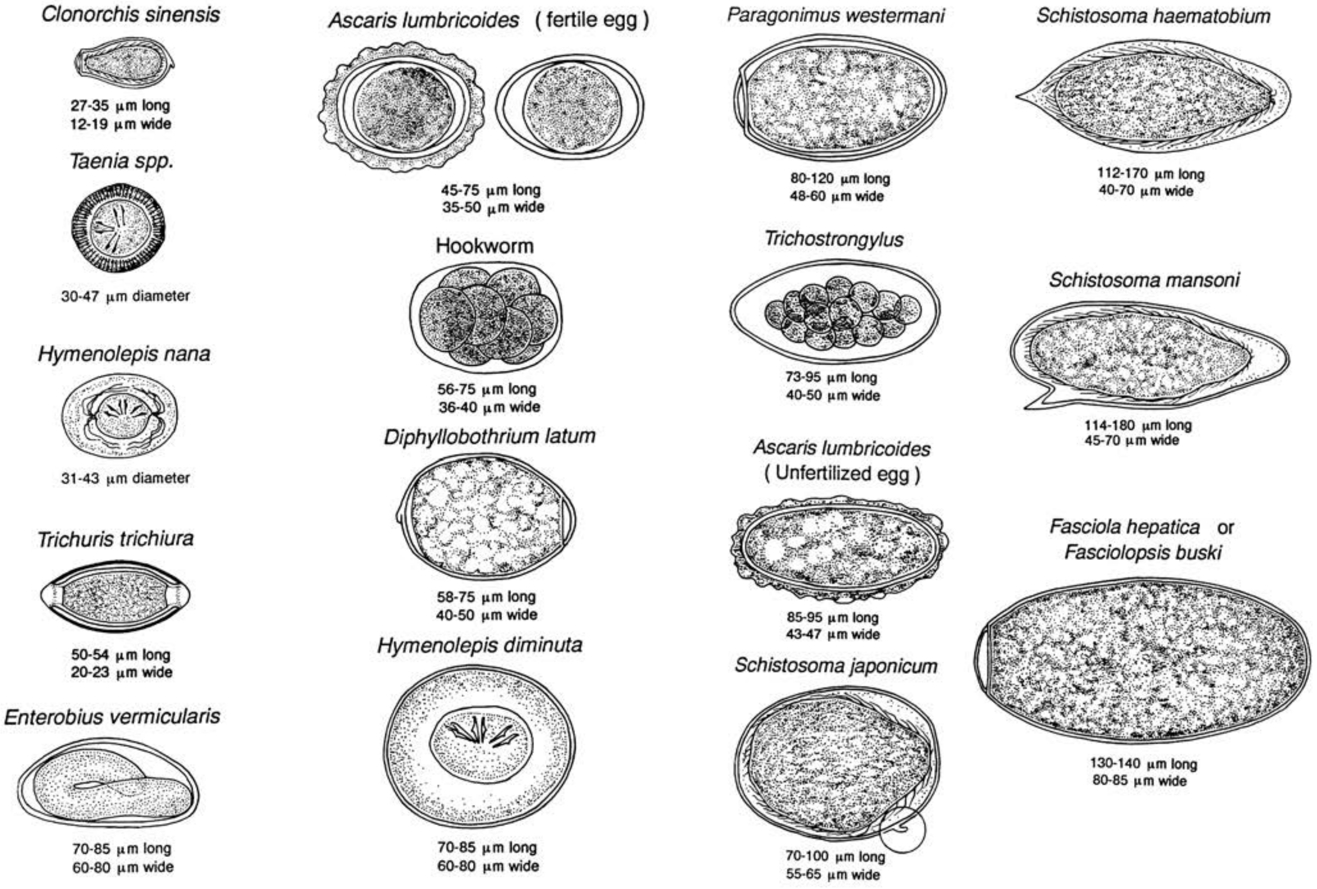

Clonorchis sinensis
27-35 µm long
12-19 µm wide
Taenia spp.
30-47 µm diameter
Hymenolepis nana
31-43 µm diameter
Trichuris trichiura
50-54 µm long
20-23 µm wide
Enterobius vermicularis
70-85 µm long
60-80 µm wide
Ascaris lumbricoides (fertile egg)
45-75 µm long
35-50 µm wide
Hookworm
56-75 µm long
36-40 µm wide
Diphyllobothrium latum
58-75 µm long
40-50 µm wide
Hymenolepis diminuta
70-85 µm long
60-80 µm wide
Paragonimus westermani
80-120 µm long
48-60 µm wide
Trichostrongylus
73-95 µm long
40-50 µm wide
Ascaris lumbricoides
(Unfertilized egg)
85-95 µm long
43-47 µm wide
Schistosoma japonicum
70-100 µm long
55-65 µm wide
Schistosoma haematobium
112-170 µm long
40-70 µm wide
Schistosoma mansoni
114-180 µm long
45-70 µm wide
Fasciola hepatica or
Fasciolopsis buski
130-140 µm long
80-85 µm wide

Figure A3.27 Relative sizes of helminth eggs.

TABLE A3.5 Adult nematodes and/or larvae found in stool specimens: size comparisons

Nematodes	Size
Ascaris lumbricoides	
Adult female	200–350 by 4–6 mm
Adult male	150–200 by 2–4 mm
Trichuris trichiura	
Adult female	35–50 mm
Adult male	30–45 mm
Enterobius vermicularis	
Adult female	8–13 mm
Adult male	2–5 mm
Hookworms (*Ancylostoma duodenale* and *Necator americanus*)	
Adult female	8–11 by 0.45 mm
Adult male	10–13 by 0.6 mm
Filariform larva	700 by 20 μm
Rhabditiform larva	250 by 20 μm
Strongyloides stercoralis	
Filariform larva	600 by 20 μm
Rhabditiform larva	250 by 20 μm
Trichinella spiralis	
Adult female	3–4 by 0.6 mm
Adult male	1.5 by 0.045 mm
Larva	90–100 by 6 μm
Microfilariae	
Wuchereria bancrofti	230–320 by 10 μm
Brugia malayi	170–260 by 5–6 μm
Loa loa	250–300 by 6–8.5 μm
Adult female	70 by 0.5 mm
Adult male	30–36 by 0.6 mm
Onchocerca volvulus	150–368 by 5–9 μm
Adult female	34–50 cm by 270–400 μm
Adult male	19–42 cm by 130–210 μm
Mansonella perstans	200 by 4.5 μm
Mansonella streptocerca	180–240 by 3 μm
Mansonella ozzardi	175–240 by 4.5 μm
Dracunculus medinensis	
Adult female	500–1,200 by 0.9–1.7 mm
Adult male	12–29 by 0.4 mm
Larva	500–750 by 15–25 μm
Gnathostoma spinigerum	
Adult female	25–54 mm
Adult male	11–25 mm

TABLE A5.3 Sources of available reagents for immunodetection of parasitic organisms or antigens[a]

Company	*Cryptosporidium* EIA or IFA	*Cryptosporidium-Giardia* combination (various methods)	*Entamoeba histolytica* EIA	*E. histolytica/ E. dispar* group EIA	*Giardia* EIA or IFA	*Crypto-Giardia* cartridge and/ or separate cartridges	*Crypto-Giardia-E. histolytica/ E. dispar* group cartridge	*Trichomonas vaginalis* (various methods)	Other parasites (methodology varies, often EIA)	Water-testing reagents
Alere (Wampole, Inverness Medical)									Binax NOW Malaria, Clearview Malaria Combo, Rapid Toxoplasma Ab	
Becton-Dickinson								X (DNA Probe) (Affirm VP III) (*Trichomonas*, *Gardnerella*, *Candida*)		
Alere (Biosite Diagnostics, Inc.)							X (Triage Parasite Panel)			
BioFire		FilmArray Gastrointestinal panel (also includes *Cyclospora*)	FilmArray Gastrointestinal panel							
Cellabs	X (IFA)	X (DFA)			X (IFA, EIA)				Filariasis Ab *Leishmania* Ag, Ab *Plasmodium* Ag, Ab *T. cruzi* Ab *Toxocara* Ab	

Hologic GenProbe							Aptima *Trichomonas* amplification assay	
Luminex, Inc.		xTAG[b]						
Medical Chemical Corp.	X	X (DFA)			X			
Meridian Diagnostics, Inc.	X	X (DFA)			X	X		
Remel (Thermo Fisher Scientific)	X	X (EIA)		X	X	X		
Sekisui Diagnostics (Genzyme Diagnostics)							OSOM Trichomonas rapid test	
TechLab, Inc./Alere	X	X (DFA, EIA, Rapid)	X		X			
Waterborne, Inc.								X

---

[a] Tests for the *Entamoeba histolytica*/*E. dispar* group or *E. histolytica* require the use of fresh or fresh, frozen stools or those submitted in Cary-Blair. All other tests (with the exception of DFA for *Cryptosporidium*/*Giardia* combination) can be used with fresh or preserved stools (formalinized base, NOT PVA; some single-vial systems may be acceptable [Universal Fixative]; consult manufacturer). Since the combination *Cryptosporidium-Giardia* tests (DFA) are based on visual recognition of the fluorescent oocysts and/or cysts, the specimens must not be frozen if fresh stools are used for testing; it is also recommended that these FA tests be performed on centrifuged stool sediment to enhance sensitivity.

[b] xTAG, multiplexed nucleic acid test that simultaneously detects 11 common viral, bacterial, and parasitic causes of infectious gastroenteritis from a single patient sample.

APPENDIX 7

“Late-Breaking” Published Information

The following information was published in the last couple of months of 2014 and the first few months of 2015 and contains relevant information for the field of diagnostic medical parasitology. This is “late-breaking” published information that may be helpful for the reader.

Intestinal Protozoa (Amebae)

Entamoeba spp.

Petropolis DB, Faust DM, Deep Jhingan G, Guillen N. 2014. A new human 3D-liver model unravels the role of galectins in liver infection by the parasite *Entamoeba histolytica*. *PLoS Pathog* **10:**e1004381. doi:10.1371/journal.ppat.1004381.

The authors developed a human three-dimensional (3D) liver *in vitro* model using cultured liver sinusoidal endothelial cells and hepatocytes in a collagen-I matrix. They found important hepatic markers and showed that the cell layers act as a biological barrier. Invasion of *Entamoeba histolytica* was investigated using wild-type strains and amebae with different virulence or adhesive properties. They demonstrated that amebic Gal/GalNAc lectin influenced the dependence of the endothelium crossing. This 3D liver model supported the molecular analysis of human cellular responses and showed for the first time the importance of the role of human galectins in the adhesion of parasites to the endothelial cells. **The presence of galectin-1 and -3 in the extracellular medium led to proinflammatory cytokine release, thus supporting the role for human galectins’ hepatic inflammatory response.** The approach in this study using a 3D liver model may be relevant for other parasitic or viral hepatic infections.

Blastocystis spp.

Bálint A, Dóczi I, Bereczki L, Gyulai R, Szücs M, Farkas K, Urbán E, Nagy F, Szepes Z, Wittmann T, Molnár T. 2014. Do not forget the stool examination!: cutaneous and gastrointestinal manifestations of *Blastocystis* sp. infection. *Parasitol Res* **113:**1585–1590.

Blastocystis spp. are the most common parasite in the human intestinal tract worldwide. The infection is characterized by diarrhea and abdominal pain; however, extraintestinal findings such as skin lesions may also be present. This study was designed to assess the frequency, clinical symptoms, and skin manifestations of confirmed positive *Blastocystis* spp. infections. Eighty patients were assessed retrospectively. The average age of the patients was 46.3 years. The number of female patients was higher than the number of males (48 versus 32; 60 versus 40%). Gastrointestinal and dermatological symptoms, biochemical tests, and hematological tests were included in the study. The skin manifestations were analyzed using descriptions, photos, and biopsies. Patients (11.25%) exhibited skin manifestations associated with *Blastocystis* spp., mainly seen in females. *Blastocystis* spp. were found in 6% of symptomatic patients between 2005 and 2013. Of the 80 patients with confirmed infection, 73.75% had gastrointestinal symptoms: 40 patients had abdominal pain and 17 had blood in their stool; other symptoms, such as excess gas (15), weight loss (8), perianal pain or itching (6), passing stool with mucus (5), vomiting (2), and fever (2), were less common. Abdominal pain in the group without skin lesions was higher than in patients with skin problems ($P = 0.007$). The mean value of C-reactive protein demonstrated elevated levels, but eosinophils were normal. Also, there were no significant differences in eosinophilia between patients with versus without skin manifestations. **Based on these results, the authors suggest a stool parasite examination for patients with skin lesions of unknown origin.**

Ruaux CG, Stang BV. 2014. Prevalence of *Blastocystis* in shelter-resident and client-owned companion animals in the US Pacific Northwest. *PLoS One* **9:**e107496. doi:10.1371/journal.pone.0107496.

It has been demonstrated that domestic dogs and cats can be infected with a number of protozoan enteric parasites, including

Blastocystis spp. For this reason, there is increased interest in *Blastocystis* as a potential enteric pathogen and in any possible role dogs and cats may play in human infections. Fecal specimens were collected from 103 shelter-resident dogs, 105 shelter-resident cats, 51 client-owned dogs, and 52 client-owned cats. *Blastocystis* was detected and subtypes identified using a nested PCR. Shelter animals were much more likely to test positive for *Blastocystis* ($P < 0.05$ for dogs, $P = 0.009$ for cats). Sequence analysis of these animals confirmed that they were carrying a number of *Blastocystis* subtypes. There was no relationship between *Blastocystis* infection and gastrointestinal symptoms in either dogs or cats. **These data suggest that shelter-companion dogs and cats are more likely to be positive for *Blastocystis* spp.** However, the data also suggest that *Blastocystis* spp. are unlikely to be major enteric pathogens in these species.

Fréalle E, El Safadi D, Cian A, Aubry E, Certad G, Osman M, Wacrenier A, Dutoit E, Creusy C, Dubos F, Viscogliosi E. 2015. Acute blastocystis-associated appendicular peritonitis in a child, Casablanca, Morocco. *Emerg Inf Dis* **21:**91–94.

This represents another case in which a *Blastocystis* sp. has been implicated as a disseminated infection (lumen, mucosa) associated with acute inflammation of the appendix. Although 26 other family members reported cases of acute to moderate gastroenteritis, diagnostic parasitology testing was not performed; thus, the definitive diagnosis in these individuals was not confirmed.

Intestinal Protozoa (Flagellates and Ciliates)

Dientamoeba fragilis

Stark D, Garcia LS, Barratt JL, Phillips O, Roberts T, Marriott D, Harkness J, Ellis JT. 2014. Description of *Dientamoeba fragilis* cyst and precystic forms from human samples. *J Clin Microbiol* **52:**2680–2683.

Dientamoeba fragilis is a common pathogenic protozoan of humans and has been reported worldwide. Although the cyst stage of the parasite has been described in an animal model, no cyst stage in humans had been described in detail from clinical samples. **In this study, the authors describe the precyst and cyst forms from human clinical samples. In light of the fact that *D. fragilis* infection can cause chronic long-term infections, these cyst forms may be involved in autoinfection.** The nuclear structure is identical to that found in *D. fragilis* trophozoites. All cysts identified were binucleate, with each nucleus containing the large central karyosome and a delicate nuclear membrane. The nucleus is often fragmented into separate chromatin granules, and chromatin is usually not seen on the nuclear membrane. However, these "true" cysts are rarely seen and identified in clinical samples. The precystic forms were more commonly seen, with a prevalence of up to 5% in human clinical specimens. This precystic form has a compact spherical shape and is up to 50% smaller than "normal" trophozoites. The precysts range in size from 4 to 5 µm, and the cytoplasm is denser and more darkly staining than is seen in normal trophozoites. Also, the cytoplasm rarely contains any inclusions.

Giardia lamblia

Liao JY, Guo YH, Zheng LL, Li Y, Xu WL, Zhang YC, Zhou H, Lun ZR, Ayala FJ, Qu LH. 2014. Both endo-siRNAs and tRNA-derived small RNAs are involved in the differentiation of primitive eukaryote *Giardia lamblia*. *Proc Natl Acad Sci USA* **111:**14159–14164.

In eukaryotes, small RNAs (sRNAs) including microRNAs and endogenous siRNAs (endo-siRNAs) regulate most biologic processes such as cell division and differentiation. The authors deep-sequenced the sRNA transcriptome of four different stages in the differentiation of *Giardia lamblia*, a very primitive eukaryote. They identified a large number of endo-siRNAs and found that they were produced from live telomeric retrotransposons and three genomic regions (i.e., endo-siRNA-generating regions [eSGRs]). Gradual upregulation of endo-siRNAs in the differentiation of *Giardia* suggests involvement in this process regulation. The authors identified five new kinds of tRNA-derived sRNAs. They also found that the biogenesis in four might correlate with previously discovered stress-induced tRNA-derived RNA (sitRNA). **These studies demonstrate a complex group of sRNAs in *G. lamblia* and further clarify the origin and evolution of eukaryotic sRNAs.**

Intestinal Protozoa (Coccidia and Microsporidia)

Cryptosporidium spp.

Yu Y, Zhang H, Guo F, Sun M, Zhu G. 2014. A unique hexokinase in *Cryptosporidium parvum*, an apicomplexan pathogen lacking the Krebs cycle and oxidative phosphorylation. *Protist* **165:**701–714.

It is well known that *Cryptosporidium parvum* may cause untreatable infections in patients with AIDS. This parasite has also been identified as one of the top four diarrheal pediatric pathogens in developing countries. *Cryptosporidium* is different from other apicomplexans such as *Plasmodium* and *Toxoplasma*, since it lacks many metabolic pathways including the Krebs cycle and cytochrome-based respiratory chain and depends on glycolysis for the production of ATP. This study reports on molecular and biochemical characteristics of a hexokinase in *C. parvum* (CpHK). Phylogeny suggests that apicomplexan hexokinases are highly divergent from those of humans and animals. CpHK differs from those in mammals and *Toxoplasma gondii* (TgHK) by preferring various hexoses and the capacity to use ATP and other NTPs. **While the exact action of 2-deoxy-D-glucose on *Cryptosporidium* requires confirmation, these data suggest that CpHK and the glycolytic pathway provide potential options for the development of anticryptosporidial therapeutics.**

Chandra V, Torres M, Ortega YR. 2014. Efficacy of wash solutions in recovering *Cyclospora cayetanensis*, *Cryptosporidium parvum*, and *Toxoplasma gondii* from basil. *J Food Prot* **77:**1348–1354.

It has been well documented that parasitic infections can originate from the ingestion of contaminated raw or processed fresh produce (herbs and fruits). Method sensitivity for organism detection on fresh produce is partially dependent on the effectiveness of the wash solutions used. In this study, six wash solutions (sterile E-Pure water, 3% levulinic acid–3% sodium dodecyl sulfate, 1 M glycine, 0.1 M phosphate-buffered saline, 0.1% Alconox, and 1% HCl-pepsin) were evaluated for their ability to remove *Cyclospora cayetanensis*, *Cryptosporidium parvum*, and *Toxoplasma gondii* from basil. Oocysts (100 or 1,000) were inoculated onto the upper surfaces of 25 g of basil leaves, placed in stomacher bags, and stored for 1 h at 21°C or 24 h at 4°C. Leaves were then hand washed in each solution for 1 min. DNA from the various wash solutions was extracted and amplified using PCR for parasite detection. Oocysts (1,000 oocysts per 25 g of basil) were detected in all wash solutions. At a concentration of 100 oocysts per 25 g, oocysts were found in 18.5 to 92.6% of the solutions. The lowest variability in oocyst recovery inoculated with 100 oocysts was seen in the 1% HCl-pepsin wash solution. Oocyst recovery was greater at 1 h than at 24 h postinoculation. **This study provides guidance for the use of wash solutions for produce, providing the most efficient retrieval of parasite oocysts.**

Ryan U, Fayer R, Xiao L. 2014. *Cryptosporidium* species in humans and animals: current understanding and research needs. *Parasitology* **141:**1667–1685.

Cryptosporidium is widely recognized as a major cause of diarrhea in developing countries. Since treatment options are very limited, control depends on an awareness of the organism biology and transmission. **Currently, 26 species are recognized on the basis of morphological, biological, and molecular studies. Of those reported in humans, *Cryptosporidium hominis* and *Cryptosporidium parvum* are responsible for the most infections. Livestock, particularly cattle, serve as an important reservoir of zoonotic infections.** However, research limitations include the lack of subtyping information for many veterinary *Cryptosporidium* species. There is limited understanding regarding host specificity of *Cryptosporidium*. The impact of climate change is also not well defined regarding organism transmission.

Sponseller JK, Griffiths JK, Tzipori S. 2014. The evolution of respiratory cryptosporidiosis: evidence for transmission by inhalation. *Clin Microbiol Rev* **27:**575–586.

Cryptosporidium infects all major vertebrates and causes significant diarrhea in humans. Children and immunodeficient individuals are more at risk for cryptosporidiosis, especially in developing countries, where high morbidity and mortality figures are seen in preschool-age children. Unfortunately, no antiprotozoal agent or vaccine exists for treatment or prevention. Respiratory cryptosporidiosis has been described in birds and mammals, including immunocompromised humans. **Respiratory cryptosporidiosis may also be seen in immunocompetent children with cryptosporidial diarrhea and unexplained cough. In addition to the traditional fecal-oral route of infection, data from animal studies, human clinical case reports, and epidemiological studies suggest respiratory transmission via secretions.** Transmission of *Cryptosporidium* oocysts may occur through inhalation or by contact with fomites contaminated by coughing, particularly since the oocysts have been found to survive for some time on fomites. Clarifying the potential role of the respiratory tract in the transmission of *Cryptosporidium* may help expand the current guidelines for disease prevention.

Chappell CL, Okhuysen PC, Langer-Curry RC, Lupo PJ, Widmer G, Tzipori S. 2015. *Cryptosporidium muris*: infectivity and illness in healthy adult volunteers. *Am J Trop Med Hyg* **92:**50–55.

Although human infections with *Cryptosporidium muris* have been reported in the literature, no definitive information has been available on clinical outcomes in healthy individuals. In this study, six healthy adult volunteers were challenged with 10^5 viable oocysts and monitored for clinical symptoms. All volunteers became infected, two suffered diarrhea, and three shed oocysts for 7 months (a longer time frame than reported with other species and volunteer infections). **Thus, it is clear that healthy individuals are susceptible to infection with *C. muris*, which causes symptoms and can become a chronic infection for many months.**

Microsporidia

Santiana M, Pau C, Takvorian PM, Cali A. 2014. Analysis of the beta-tubulin gene and morphological changes of the microsporidium *Anncaliia algerae* both suggest albendazole sensitivity. *J Eukaryot Microbiol* **62:**60–68.

***Anncaliia algerae*, an obligate intracellular microsporidian parasite, is an opportunistic human pathogen;** however, therapy has not been assessed. Albendazole is an antitubulin polymerization drug used for helminth infections and is the drug of choice for some human microsporidial infections. Results vary from organism clearance (*Encephalitozoon*) to resistance (*Enterocytozoon*). This study investigated albendazole efficacy on *A. algerae* infection in rabbit kidney (RK13) cells and human fetal lung (HFL-1) fibroblasts. This drug is effective on *A. algerae*, and the 50% inhibitory concentration in RK13 cells is 0.1 μg/ml. Long-term therapy can inhibit 98% spore production; however, if the treatment is interrupted, the infection is reestablished without documented additional patient exposures. The *A. algerae* beta-tubulin gene was purified, cloned, and then sequenced. Specific amino acids linked to benzimidazole sensitivity (five out of six) are conserved in *A. algerae*. **Although these data suggest that *A. algerae* is sensitive to albendazole,** organisms in culture are not completely eliminated.

Hocevar SN, Paddock CD, Spak CW, Rosenblatt R, Diaz-Luna H, Castillo I, Luna S, Friedman GC, Antony S, Stoddard RA, Tiller RV, Peterson T, Blau DM, Sriram RR, da Silva A, de Almeida M, Benedict T, Goldsmith CS, Zaki SR, Visvesvara GS, Kuehnert MJ, Microsporidia Transplant Transmission Investigation Team. 2014. Microsporidiosis acquired through solid organ transplantation: a public health investigation. *Ann Intern Med* **160:**213–220.

Encephalitozoon cuniculi **has been associated with renal, respiratory, and central nervous system infections in immunosuppressed patients. This microsporidian has also been identified as causing illness among three recipients of solid organ transplants from a single donor.** Appropriate specimens were examined via culture, immunofluorescent antibody, PCR, immunohistochemistry, and electron microscopy. Medical records from the donor were reviewed, as were answers from a clinically relevant questionnaire. Kidneys and lungs from the donor were transplanted to three recipients. Subsequently, the recipients became symptomatic with fever approximately 7 to 10 weeks posttransplantation. Urine cultures, serologic results, and PCR testing from the three recipients were all positive for *E. cuniculi,* genotype III. *E. cuniculi* was also confirmed in all biopsy and autopsy specimens. Although autopsy specimens were not available, serologic test results for *E. cuniculi* were also found from the donor. The recipients were treated with albendazole. Assessment of the donor information failed to confirm specific factors related to the suspected *E. cuniculi* infection. Microsporidiosis has now been confirmed as an emerging transplant-associated disease and should be considered in symptomatic transplant recipients. **Possible donor-derived disease assessment is critical, especially when multiple recipients from a common donor become symptomatic.**

Watts MR, Chan RC, Cheong EY, Brammah S, Clezy KR, Tong C, Marriott D, Webb CE, Chacko B, Tobias V, Outhred AC, Field AS, Prowse MV, Bertouch JV, Stark D, Reddel SW. 2014. *Anncaliia algerae* microsporidial myositis. *Emerg Infect Dis* **20:**185–191.

The microsporidian *Anncaliia algerae* was documented in 2004 as causing fatal myositis in an immunosuppressed patient from Pennsylvania. Two cases were later reported, and the authors reveal two additional cases, including one nonfatal case. All five cases were investigated, including clinical findings, diagnosis, and management; life cycle and epidemiology information was also summarized. **Prior to infection, all patients were immunosuppressed due to relevant therapy for rheumatoid arthritis or solid organ transplantation.** Four of the five patients were from Australia. The diagnosis was confirmed from skeletal muscle biopsies. The surviving patient was treated with albendazole and had immunosuppressive drugs reduced. While insects serve as the normal hosts for *A. algerae*, it has been suggested that human contact with water contaminated by *A. algerae* spores may lead to infections. **Therefore, *A. algerae* has been documented as causing human myositis, particularly in coastal areas in Australia.**

Cystoisospora (*Isospora*)

Lindsay DS, Houk AE, Mitchel SM, Dubey JP. 2014. Developmental biology of *Cystoisospora* (*Apicomplexa*: *Sarcocystidae*) monozoic tissue cysts. *J Parasitol* **100:**392–398.

Tissue cyst stages form an integral part of the developmental cycle and potential transmission of *Sarcocystidae* species. Tissue cysts within these species (*Toxoplasma*, *Hammondia*, *Neospora*, *Besnoitia*, and *Sarcocysti*) contain many infectious stages (bradyzoites). The tissue cyst stage of *Cystoisospora* (syn. *Isospora*) has one infectious stage (zoite) and is therefore referred to as a monozoic tissue cyst (MZTC). No tissue cyst stages are known for the *Nephroisospora*. The current report looks at the developmental biology of MZTC stages of *Cystoisospora* Frenkel, 1977, the cause of intestinal coccidiosis in cats, dogs, pigs, and humans. **These MZTC stages of *Cystoisospora belli* are possibly associated with human clinical disease reoccurrence.** Developmental stages that are found in low numbers in immunocompetent definitive human hosts tend to be much more numerous in immunosuppressed humans. It is anticipated that additional studies will lead to a clarification of *C. belli* infections in immunocompromised patients, as well as any life cycle mechanisms associated with possible reoccurrence of disease.

Sarcocystis spp.

Lingappa HA, Krishnamurthy A, Puttaveerachary AK, Govindashetty AM, Sahni S. 2015. Foray of cytologically diagnosed intramuscular sarcocystosis—a rarity. *J Clin Diagn Res* **9:**ED11–ED12.

While human cases with *Sarcocystis* spp. are uncommon, these organisms are well documented to cause intestinal and muscular problems. In this particular patient, an intramuscular swelling in the lumbar region was diagnosed through cytology as intramuscular sarcocystosis; this finding was later confirmed from histopathology. This case emphasizes the importance of fine needle aspiration cytology in differentiating sarcocystosis from other intramuscular parasites. **In this case, the overall parasite morphology was more definitive from the cytology smears than the traditional paraffin sections and strongly suggests the benefits of using fine needle aspirate cytology.** There are excellent images in this particular article.

Fayer R, Esposito DH, Dubey JP. 2015. Human infections with *Sarcocystis* species. *Clin Microbiol Rev* **28:**295–311.

Recurrent outbreaks of human cases of muscular sarcocystosis in travelers to Malaysia have led to increased interest in this disease. The *Sarcocystis* life cycle requires two hosts, definitive and intermediate; humans can serve as definitive hosts with intestinal sarcocystosis (*Sarcocystis hominis* from beef, and *Sarcocystis suihominis* from pork). Humans serve as intermediate hosts for *Sarcocystis nesbitti* (reptile definitive host, and possibly other unidentified species) acquired by ingesting sporocysts from feces-contaminated food or water and the environment. **It is important to consider this infection in patients with a relevant travel history to tropical areas of the world, particular if they present with elevated serum enzyme levels and eosinophilia.**

Protozoa from Other Body Sites

Free-Living Amebae

Robaei D, Carnt N, Minassian DC, Dart JK. 2014. The impact of topical corticosteroid use before diagnosis on the outcome of *Acanthamoeba* keratitis. *Ophthalmology* **121:**1383–1388.

Corticosteroid use prior to the diagnosis of *Acanthamoeba* keratitis (AK) is strongly linked to a worse visual outcome. This situation often occurs due to the initial misdiagnosis of AK as herpetic keratitis. It is clinically critical to include AK in the differential diagnosis of keratitis causative agents, particularly before diagnosing herpes keratitis and instituting the subsequent use of topical corticosteroids.

Van der Beek NA, van Tienen C, de Haan JE, Roelfsema J, Wismans PJ, van Genderen PJJ, Tanghe HL, Verdijk RM, Titulaer MJ, van Hellemond JJ. 2015. Fatal *Balamuthia mandrillaris* meningoencephalitis in the Netherlands after travel to The Gambia. *Emerg Infect Dis* **21:**896–898.

Up to this point, meningoencephalitis caused by *Balamuthia mandrillaris* had not been reported from Africa. Unlike *Acanthamoeba* encephalitis, *Balamuthia* amebic encephalitis has been found in immunocompetent individuals. These findings confirm the virulence of this pathogen. In immunocompetent hosts, an inflammatory response is mounted and amebae are surrounded by macrophages, lymphocytes, and neutrophils. However, with rare exceptions, these patients also tend to die of severe central nervous system disease. Findings are often nonspecific, including an elevated cerebrospinal fluid protein and low cerebrospinal fluid glucose. **Infection with this organism should be considered in unexplained cases of meningoencephalitis, including those in immunocompetent patients.** In areas of the world where reports are lacking or are minimal, the infection may go unrecognized.

Trichomonas vaginalis

Hathorn E, Ng A, Page M, Hodson J, Gaydos C, Ross JD. 2014. A service evaluation of the Gen-Probe APTIMA nucleic acid amplification test for *Trichomonas vaginalis*: should it change whom we screen for infection? *Sex Transm Infect* **91:**81–86.

This study involves evaluation of the Gen-Probe APTIMA nucleic acid amplification test used to determine the prevalence of *Trichomonas vaginalis* infection in a United Kingdom sexual health clinic. Also, a part of the study was designed to identify possible risk factors to develop an appropriate patient screening strategy. Patients (new clinical episode) were offered the Aptima test as well as routine screening. Asymptomatic females submitted a self-collected vulvovaginal specimen, and asymptomatic men submitted a first-void urine sample. A urethral swab was taken from symptomatic men, and two posterior vaginal swabs from symptomatic females (Aptima and culture). Data were collected from all patients who were positive for *T. vaginalis* infection, as well as 100 randomly selected *T. vaginalis*–negative controls. The prevalence of *T. vaginalis* infection was 21/1,483 (1.4%) (95% confidence interval [CI], 0.9% to 2.2%) in men and 72/2,020 (3.6%) (95% CI, 2.8% to 4.5%) in women. The *T. vaginalis* positivity rate was higher in black Caribbean patients when compared with Caucasian patients (men 5.4% versus 0.1%, $P < 0.001$; women 9.0% versus 1.2%, $P < 0.001$). Compared to culture results, the Aptima test detected 16 more infections (38%) in symptomatic women. **Although more inclusive screening with the Aptima test will identify additional *T. vaginalis* infections, prevalence in the UK is low, and the extra screening may not prove to be cost-effective. However, testing of symptomatic patients and those within high-risk asymptomatic groups may be clinically warranted.**

Nathan B, Appiah J, Saunders P, Heron D, Nichols T, Brum R, Alexander S, Baraitser P, Ison C. 2014. Microscopy out performed in a comparison of five methods for detecting *Trichomonas vaginalis* in symptomatic women. *Int J STD AIDS* **26:**251–256.

This study was designed to compare five methods (an in-house PCR, the Aptima *T. vaginalis* kit, the OSOM Trichomonas Rapid Test, culture, and microscopy) to detect *Trichomonas vaginalis* infection in symptomatic women. A true positive was defined as any sample that was positive for *T. vaginalis* by two or more methods. Of 246 women, 24 were found positive for *T. vaginalis* by two or more different methods. From this group of 24 patients, 21 were real-time PCR positive (sensitivity 88%), 22 were Aptima *T. vaginalis* positive (sensitivity 92%), 22 were OSOM positive (sensitivity 92%), 9 were wet mount microscopy positive (sensitivity 38%), and 21 were culture positive (sensitivity 88%). Two patients were not considered true positives, because they were positive using one method only. **All methods demonstrated a sensitivity that was significantly greater than that obtained using wet mount microscopy. Thus, many symptomatic cases are routinely missed if microscopy is the only method used for the diagnosis of trichomoniasis.**

Secor WE, Meites E, Starr MC, Workowski KA. 2014. Neglected parasitic infections in the United States: trichomoniasis. *Am J Trop Med Hyg* **90:**800–804.

Trichomonas vaginalis is the most prevalent nonviral sexually transmitted infection within the United States. However, the problems associated with this infection are not thoroughly understood, and the infection receives too little attention regarding public health issues. Serious infection sequelae include an increased risk of infection with HIV and unfavorable pregnancy outcomes such as premature rupture of the membranes, preterm labor, and low-birth-weight infants. **Newly developed diagnostic tests have improved the diagnosis, but infections in males require additional study and clarification.** Other issues that need additional investigation include the epidemiology of trichomoniasis in both sexes, defining the actual public health impact of symptomatic and asymptomatic *T. vaginalis* infections, and therapeutics and their efficacy in reducing the overall costs of this disease. **Other important issues for clarification include resistance versus noncompliance with therapy and the probability of reinfection.**

Tissue Protozoa

Toxoplasma gondii

McAuley JB. 2014. Congenital toxoplasmosis. *J Pediatric Infect Dis Soc* **3:**S30–S35.

Infection with *Toxoplasma gondii* is a very common human parasitic infection; however, patients generally remain asymptomatic. Serious sequelae in a pregnant woman with a primary infection, particularly early in the pregnancy, can cause very serious disease in the developing fetus. These potential problems, including organism potential infectivity and severity of symptoms, have recently been linked to various *Toxoplasma* genotypes. Risk factors, including foodborne transmission, have been more thoroughly investigated and defined. Early diagnosis in infected pregnant women, followed by recommended therapy, has decreased mother-to-child transmission. The addition of immunoglobulin G avidity testing has also produced improved diagnostic testing and better clinical outcomes during pregnancy. It is now well documented that the infected child can be treated *in utero* and through the first year of life. **However, regardless of our more complete comprehension of congenital disease, other issues remain problematic and require clarification. These include the development of enhanced diagnostic tests, the need for more effective therapy, clearly defined screening protocols for pregnant women, and food safety recommendations for disease prevention.**

Davis SM, Anderson BL, Schulkin J, Jones K, Eng JV, Jones JL. 2014. Survey of obstetrician-gynecologists in the United States about toxoplasmosis: 2012 update. *Arch Gynecol Obstet* **291:**545–555.

The American College of Obstetricians and Gynecologists (ACOG) surveyed a number of their members to establish current knowledge, practices, opinions, and educational preferences regarding toxoplasmosis during pregnancy. Among the respondents, 80.2% had reported no acute maternal *Toxoplasma gondii* infections during the past 5 years, 12.7% correctly identified the clinical relevance of the *Toxoplasma* avidity test for screening, and 42.6% performed *T. gondii* serologies for some asymptomatic pregnant women. Respondents in the northeastern United States were twice as likely to use routine screening when compared with those in the west; female physicians were one and a half times more likely than male physicians to use routine screening. Most practitioners felt that updated ACOG guidelines on screening and management for pregnant women with acute toxoplasmosis would support educational efforts related to this infection. Additional information related to risk factor counseling would also be helpful.

Plasmodium and *Babesia* spp.

Plasmodium spp.

Vythilingam I, Lim YA, Venugopalan B, Ngui R, Leong CS, Wong ML, Khaw L, Goh X, Yap N, Sulaiman WY, Jeffery J, Zawiah AG, Nor Aszlina I, Sharma RS, Yee Ling L, Mahmud R. 2014. *Plasmodium knowlesi* malaria an emerging public health problem in Hulu Selangor, Selangor, Malaysia (2009-2013): epidemiologic and entomologic analysis. *Parasit Vectors* **7:**436.

A review of 100 *Plasmodium knowlesi*/*Plasmodium malariae* cases over a 5-year period in the Hulu Selangor district found these cases to be predominantly seen among young adults (ages 20 to 39 years; 67 cases; 67%); no deaths were reported. In most cases, the individuals worked in agriculture and forestry (51; 51%). Information based on the examination of 535 mosquitoes indicated *Anopheles maculatus* was the predominant species (49.5%), followed by *Anopheles letifer* (13.1%) and *Anopheles introlatus* (11.6%). Only *A. introlatus* was positive for *Plasmodium* oocysts. The authors demonstrated that *P. knowlesi* hotspot areas overlapped with areas where the infected *A. introlatus* was found, thus strongly supporting the hypothesis that *A. introlatus* is the vector for *P. knowlesi* in the Hulu Selangor district. Unfortunately, without additional information on the vectors and macaques, effective control measures will be difficult to implement. The use of a GIS (geographic information system) will be useful in defining these hotspot areas for control implementation. **Therefore, *A. introlatus* has been implicated as a vector of *P. knowlesi* in Hulu Selangor. These cases of *P. knowlesi* continue to increase.**

Nakaviroj S, Kobasa T, Teeranaipong P, Putaporntip C, Jongwutiwes S. 2015. An autochthonous case of severe *Plasmodium knowlesi* malaria in Thailand. *Am J Trop Med* **92:**569–572.

The patient was a 58-year-old man who presented with fever, hypotension, renal failure, jaundice, and severe thrombocytopenia. The patient's parasitemia on admission was 16.67%, a very high percentage. *Plasmodium knowlesi* is unique among the primate and human malarias in that it has a 24-h erythrocytic cycle, which tends to accelerate the development of complications. Since *P. knowlesi* malaria can progress rapidly to severe disease, these cases should be treated like *Plasmodium falciparum* malaria if the species identification is based on microscopic examination alone or if coinfection with *P. falciparum* cannot be excluded with certainty using PCR. **It is important to remember that diagnostic results should include a comment: "Unable to rule out *P. falciparum* or *P. knowlesi*." This information alerts the physician to the possibility of severe disease and possible fatal outcomes.**

Maude RJ, Nguon C, Dondorp AM, White LJ, White NJ. 2014. The diminishing returns of atovaquone-proguanil for elimination of *Plasmodium falciparum* malaria: modelling mass drug administration and treatment. *Malar J* **13:**380.

Artemisinin resistance has been identified as a major problem in the elimination of *Plasmodium falciparum* malaria, which depends on the use of artemisinin combination therapy (ACT). In areas where artemisinin-resistant *P. falciparum* occurs, atovaquone-proguanil (A-P) has been recommended as an alternative to ACT. However, a single point mutation in the cytochrome *b* gene is responsible for resistance to atovaquone. Even a single round of mass drug administration (MDA) with A-P could lead to resistance. Within 4 to 5 years, the use of A-P for symptomatic patients could result in complete therapeutic failure. **Therefore, to achieve malaria elimination, A-P for MDA or treatment of symptomatic patients should be discouraged. A combination strategy using ACT for treatment of symptomatic patients, insecticide-impregnated bed nets, and ACT+P MDA is recommended.**

Kobylinski KC, Alout H, Foy BD, Clements A, Adisakwattana P, Swierczewski BE, Richardson JH. 2014. Rationale for the coadministration of albendazole and ivermectin to humans for malaria parasite transmission control. *Am J Trop Med Hyg* **91:**655–662.

It has been established that infections with soil-transmitted helminths (STHs) increase the risk for malaria; STHs may also increase the efficacy of malaria transmission. With the potential for developing more pronounced anemia in patients who have both infections and the potential for pregnancy outcome complications, it has been suggested that the **addition of ivermectin mass drug administration added to the administration of albendazole would serve as a potential malaria control mechanism through elimination of STHs.**

Price RN, von Seidlein L, Valecha N, Nosten F, Baird JK, White NJ. 2014. Global extent of chloroquine-resistant *Plasmodium vivax*: a systematic review and meta-analysis. *Lancet Infect Dis* **14:**982–991.

In most areas of endemicity, chloroquine remains the first-line drug for *Plasmodium vivax* malaria; however, resistance continues to increase. In infections with *P. vivax*, determination of therapeutic success is complicated by a potential relapse from the dormant liver stages. The authors identified 129 eligible clinical trials involving 21,694 patients at 179 study sites and 26 case reports describing 54 patients. They identified chloroquine-resistant areas in 58 (53%) of 113 study sites, which were seen in most countries where *P. vivax* was endemic. Organism clearance in 95% of patients by day 2 or 100% of patients by day 3 was correct in predicting chloroquine sensitivity. Unfortunately, varying study designs and data analysis have been somewhat confusing in the surveillance of chloroquine-resistant *P. vivax*. Improved methods for tracking chloroquine resistance in these areas are necessary for the development of improved malaria therapeutics.

Gonçalves LA, Cravo P, Ferreira MU. 2014. Emerging *Plasmodium vivax* resistance to chloroquine in South America: an overview. *Mem Inst Oswaldo Cruz* **109:**534–539.

The global emergence of *Plasmodium vivax* strains resistant to chloroquine definitely impacts current international approaches to malaria control and eradication. **These strains are highly endemic in Indonesia, East Timor, and Papua New Guinea. In addition, chloroquine-resistant *P. vivax* infections have also been confirmed in Guyana, Peru, and Brazil.** The authors discuss chloroquine resistance throughout areas of *P. vivax* endemicity in Latin America. They also include the molecular mechanisms of chloroquine resistance in *P. vivax*, as well as the potential development of dependable molecular drug resistance markers that can predict therapeutic outcomes.

Khim N, Andrianaranjaka V, Popovici J, Kim S, Ratsimbasoa A, Benedet C, Barnadas C, Durand R, Thellier M, Legrand E, Musset L, Menegon M, Severini C, Nour BY, Tichit M, Bouchier C, Mercereau-Puijalon O, Menard D. 2014. Effects of mefloquine use on *Plasmodium vivax* multidrug resistance. *Emerg Infect Dis* **20:**1629–1636.

Although drug resistance is well documented in *Plasmodium falciparum*, the inability to culture *Plasmodium vivax* limits our understanding of drug resistance in this species. In areas where mefloquine has been used as a monotherapy or in combination with artemisinin, mefloquine resistance has been detected. To determine the impact of chloroquine resistance on *P. vivax*, the authors used PCR for the assessment of *P. vivax mdr-1* gene copies for the evaluation of this gene as an indicator of *P. vivax* in patients documented to have received chloroquine. Currently, mefloquine has been used for chemoprophylaxis in over 35 million travelers from France, alone. *P. falciparum mdr-1* gene amplification is the primary mechanism of mefloquine resistance in this species; in areas where mefloquine has been widely used, *P. vivax mdr-1* amplification is frequent and detected in high numbers of isolates. **Similar to results for atovaquone resistance, data from this study suggest that *PVmdr-1* amplification is probably faster than previously thought, thus possibly leading to an increase of mefloquine resistance in *P. vivax*.**

Jaurequiberry S, Ndour PA, Roussel C, Ader F, Safeukui I, Nguyen M, Biliqui S, Ciceron L, Mouri O, Kendjo E, Bricaire F, Vray M, Angoulvant A, Mayaux J, Haldar K, Mazier D, Danis M, Caumes E, Thellier M, Buffet P, French Artesunate Working Group. 2014. Postartesunate delayed hemolysis is a predictable event related to the lifesaving effect of artemisinins. *Blood* **124:**167–175.

It has been well documented that patients with severe malaria treated with artesunate may experience delayed hemolysis (1 to 3 weeks post-therapy) with pitting, a splenic process during which dead organisms are removed from red blood cells. These patients are often nonimmune travelers rather than patients who live in areas of endemicity. The authors monitored 123 patients treated for severe malaria with artesunate. Thirteen of sixty (22%) nontransfused patients had delayed hemolysis. **Health care workers need to be aware of potential complications, which strongly suggest extended patient follow-up for potential hemolytic problems associated with the use of artesunate.**

Fuehrer HP, Noedl H. 2014. Recent advances in detection of *Plasmodium ovale*: implications of separation into the two species *Plasmodium ovale wallikeri* and *Plasmodium ovale curtisi*. *J Clin Microbiol* **52:**387–391.

Plasmodium ovale is endemic in most countries where malaria is endemic in southern and southeastern Asia, and both classic (*P. ovale curtisi*) and variant (*P. ovale wallikeri*) types have been seen. Molecular phylogenetic data indicate that *P. ovale* malaria is caused by two closely related species. The authors review various methods for the molecular diagnosis of malaria, emphasizing the detection of *P. ovale wallikeri* and *P. ovale curtisi*. Both species occur in Africa, as well; dual infections with both organisms have been documented. Although the two species cannot be differentiated on the basis of morphology, they have been reported to vary in terms of latency. An update for the widely used NP-1993 to NP-2005 (SSU rRNA) protocols for all human malaria parasites is discussed, specifically discussing the two primers (rOVA1WC and rOVA2WC) that bind to the two *P. ovale* species but do not bind to other human malaria parasites. **If two different PCRs for *P. ovale curtisi* and *P. ovale wallikeri* are inaccessible, the *P. ovale* sp. should be identified using techniques designed to detect both species. In this case, a more definitive answer should be obtained if possible as follow-up testing.**

Ta TH, Hisam S, Lanza M, Jiram AI, Ismail N, Rubio JM. 2014. First case of a naturally acquired human infection with *Plasmodium cynomolgi*. *Malar J* **13:**68–75.

Since 1960, seven species of simian malaria have been confirmed to be transmissible from mosquito to human: *Plasmodium cynomolgi*, *Plasmodium brasilianum*, *Plasmodium eylesi*, *Plasmodium knowlesi*, *Plasmodium inui*, *Plasmodium schwetzi*, and *Plasmodium simium*. However, *P. knowlesi* is the only one that infects humans in nature. **The authors report the first known case of a human naturally acquired *P. cynomolgi* malaria infection.** The patient was a 39-year-old female from a nonendemic area, had no history of malaria, and reported no travel to possible endemic areas. Stained thick and thin blood films revealed *P. malariae/P. knowlesi*. However, the diagnosis of *P. vivax* was confirmed by a nested PCR assay. Using another PCR assay plus sequencing confirmed that the patient was infected with *P. cynomolgi* and not with *P. vivax*. This is the first report of human *P. cynomolgi* infection acquired via mosquito bite. However, other similar cases may remain undiagnosed or misdiagnosed, since *P. cynomolgi* cannot be differentiated morphologically from *P. vivax*. Also, depending on the molecular test used, the diagnosis could also be *P. vivax* in error.

Muller M, Schlagenhauf P. 2014. *Plasmodium knowlesi* in travellers: update 2014. *Int J Inf Dis* **22:**55–64.

This infection has taken on added importance for travelers; *Plasmodium knowlesi* imported infections have been reported in many areas worldwide outside of the documented areas of endemicity. From a detailed study of 103 publications, the following facts were found: the time spent in the endemic areas was from 1 week to several months and included travel to a forested area with overnight stays. These travelers were from Sweden, Finland, Spain, France, the Netherlands, Germany, Australia, New Zealand, and the United States; most patients were males. While fever and chills were reported in 100% of the patients, headache, rigors, malaise, anorexia, myalgia, arthralgia, cough, abdominal pain, tachycardia, and tachypnea were also reported. Although thick and thin blood films remain the tests of choice, there can be confusion since *P. knowlesi* resembles *P. falciparum* in the early red blood cell stages and *P. malariae* in the later red blood cell stages. Unfortunately, the rapid malaria tests have limited sensitivity in distinguishing nonfalciparum species. **This review covers all aspects of *P. knowlesi* malaria in travelers and will help clarify this infection and its sequelae.**

Moreno A, Joyner C. 2015. Malaria vaccine clinical trials: what's on the horizon. *Curr Opin Immunol* **35:**98–106.

Although significant progress has been made regarding potential malaria vaccines, much work remains. This review contains extensive information on completed and ongoing vaccine trials, as well as information on newly discovered vaccine candidates.

Babesia spp.

Apostolou A, Sorhage F, Tan C. 2014. Babesiosis surveillance, New Jersey, USA, 2006–2011. *Emerg Infect Dis* **20:**1407–1409.

During 2006 to 2011, 568 babesiosis cases were reported in New Jersey: 521 (92%) confirmed and 47 (8%) probable. In 2006 and 2011, 64 (0.76/100,000) and 166 (1.97/100,000) cases were reported, a figure that represents a 260% increase. Seven counties accounted for 462 (81%) of the reported cases, and 128/166 (77%) reported cases occurred in 2011. While all 21 counties reported at least 1 case in 2006 to 2011, only 8 counties reported any cases from 1993 to 2001. Counties in southern New Jersey reported most of the babesiosis cases; these same counties also reported a higher prevalence of Lyme disease. It has been well documented that the relevant ticks can carry and transmit both infections at the same time. Although babesiosis is found in both eastern and western areas within the United States, expanded surveillance throughout the whole area is recommended, particularly when related to potential donor transfusion cases. The majority of babesiosis cases in this report were seen during the summer; however, documentation of transfusion cases was confirmed during the entire year. Adding babesiosis to the list of reportable diseases will enhance current reporting practices and will support efforts to redefine the overall epidemiology of this disease.

Schmidt M, Geilenkeuser WJ, Sireis W, Seifried E, Hourfar K. 2014. Emerging pathogens: how safe is blood? *Transfus Med Hemother* **41:**10–17.

For many years, the issue of donated blood safety was primarily focused on the possible transmission of HIV. However, if considering other potential transfusion-related infections, malaria, dengue virus, *Trypanosoma cruzi* (Chagas' disease), and *Babesia* spp. also need to be included. More than 300 million to 500 million individuals throughout the world are infected with malaria, and 1.5 million to 2.7 million people a year, half of whom are children under the age of 5, die from the disease. Dengue virus, which causes hemorrhagic fever and shock syndrome, infects more than 50 million people each year. Chagas' disease caused by *Trypanosoma cruzi* occurs primarily in South America and infects roughly 10 million people each year; this infection is now endemic in North America, both as a natural infection and related to immigration into the United States and Canada.

Babesia spp. cause a parasitic infection that resembles malaria infection. While patients with babesiosis usually remain asymptomatic, severe disease has been reported in those who may be immunocompromised, including the elderly and very young. The use of detection systems for all of these organisms related to donor screening becomes very costly and time consuming. Another approach recommends organism inactivation in donor blood, which may provide a comprehensive solution for potential blood-borne pathogens. This approach will also decrease the potential loss of blood donors through the deferral process.

Leishmania spp.

Castelli G, Galante A, Lo Verde V, Migliazzo A, Reale S, Lupo T, Piazza M, Vitale F, Bruno F. 2014. Evaluation of two modified culture media for *Leishmania infantum* cultivation versus different culture media. *J Parasitol* **100:**228–230.

This publication reports on the use of improved culture media for *Leishmania* promastigotes that eliminates the need for Evans' modified Tobie's medium (EMTM), liquid RPMI 1640, and Peptone-yeast extract medium (P-Y). Although EMTM supports parasite growth very well, it is complicated to prepare and requires fresh rabbit blood. RPMI 1640 and P-Y do not support parasite growth as well as EMTM. The authors provide information on new media modifications, called RPMI-PY and Tobie-PY for the growth of *Leishmania*. **Based on comparisons of the classic culture media to the new media, RPMI-PY and Tobie-PY, results indicate that the new media provide faster and more abundant growth.**

Saroufim M, Charafeddine K, Issa G, Khalifeh H, Habib RH, Berry A, Ghosn N, Rady A, Khalifeh I. 2014. Ongoing epidemic of cutaneous leishmaniasis among Syrian refugees, Lebanon. *Emerg Infect Dis* **20:**1712–1715.

The authors have documented a cutaneous leishmaniasis outbreak that began among Syrian refugees in Lebanon in September of 2012. Patients (1,275) from 213 refugee families were placed into three groups: those in whom leishmaniasis was diagnosed, confirmed, and treated; those in whom leishmaniasis was diagnosed, confirmed, and not treated; and those in whom leishmaniasis was not diagnosed. For 948 patients from the undiagnosed group, clinical specimens were obtained using punch biopsies for microscopic examination and molecular confirmation. The authors identified *Leishmania tropica* in 85%, a species causing large facial lesions and prolonged disease requiring systemic rather than localized therapy, and *Leishmania major* in 15% of patients. **After 3 months of megulamine antimonate therapy, the cure rate was 82%, with 80% of the patients receiving intralesional therapy and 20% receiving intramuscular therapy.** Risk factors for cutaneous leishmaniasis include many conditions facing refugee populations, including poverty, malnutrition, inadequate sanitation, underlying illness, and inadequate housing. Unfortunately these conditions support the sandfly vectors of *L. tropica*, and leishmaniasis becomes a tremendous problem for these populations.

Glazer Y, Gandacu D, Anis E, Karakis I, Warshavsky B, Slater P, Grotto I. 2014. Resurgence of cutaneous leishmaniasis in Israel, 2001–2012. *Emerg Infect Dis* **20:**1605–1617.

Cutaneous leishmaniasis has been endemic in Israel for many years, and the disease is known as the "Rose of Jericho." **However, after a relatively stable incidence rate of 0.4/100,000 population in 2001, the rate increased in 2012 to 4.4/100,000 population. Also, the disease became more numerous in areas with limited previous reports.** Based on an extensive epidemiologic analysis of the cases submitted, the authors reported an expansion of *Leishmania major* infections throughout the southern part of Israel and more concentrated outbreaks with *Leishmania tropica* in the northern part of Israel. Increased incidence of *L. tropica* has also been reported from other countries in the Mediterranean Basin. Increases in cutaneous leishmaniasis are often linked to migration, urbanization, deforestation, climate change, and improved disease diagnosis. Certainly, changes in the population dynamics of the sand fly vectors probably play a large role in disease epidemiology.

Martin-Blondel G, Iriart X, El Baidouri F, Simon S, Mills D, Demar M, Pistone T, Le Taillandier T, Malvy D, Gangneus J, Couppie P, Munckhof W, Marchou B, Ravel C, Berry A. 2015. Outbreak of *Leishmania braziliensis* cutaneous leishmaniasis, Saül, French Guiana. *Emerg Inf Dis* **21:**892–894.

A documented increase and geographic expansion of *Leishmania braziliensis* in French Guiana are associated with the need for species-specific identification of the causative agent. This organism is responsible for involving the mucous membranes of the lips, nose, soft palate, and larynx. Unfortunately, *L. braziliensis* is refractive to pentamidine isethionate, which is the primary drug used for *Leishmania guyanensis* in the same geographic area. **Clinical cases of cutaneous leishmaniasis from this region require careful diagnosis and appropriate therapy, both of which are subject to error.**

Trypanosoma spp.

African Trypanosomiasis

Franco JR, Simarro PP, Diarra A, Jannin JG. 2014. Epidemiology of human African trypanosomiasis. *Clin Epidemiol* **6:**257–275.

Human African trypanosomiasis (HAT) is caused by *Trypanosoma brucei gambiense*, which is a chronic form of the disease present in western and central Africa (including actual sleeping sickness syndrome), and by *Trypanosoma brucei rhodesiense*, which is an acute disease located in eastern and southern Africa (much higher morbidity than the western form). While the eastern form has many game animals involved as reservoirs, the western form is characterized by humans being the main reservoir. In the gambiense form 98% of the cases are reported, with 75% of the cases coming from the Democratic Republic of the Congo. This infection is seen in defined rural areas that are located in sub-Saharan Africa. The risk of infection is influenced by the interaction of the infected tsetse fly with the potential human host. **After a series of outbreaks and disease resurgence and control, elimination of the gambiense form of HAT is thought to be a possibility by 2030. However, since the rhodesiense form of HAT is a zoonosis involving many animal reservoirs, control of this infection is much less likely, even with more concentrated control efforts over time.**

American Trypanosomiasis

Andrade DV, Gollob KJ, Dutra WO. 2014. Acute Chagas' disease: new global challenges for an old neglected disease. *PLoS Negl Trop Dis* **8:**e3010. doi:10.1371/journal.pntd.0003010.

Chagas' disease is caused by the bloodborne protozoan *Trypanosoma cruzi*, with approximately 7 to 8 million cases worldwide. This disease continues to expand its geographic range and remains a serious global public health problem. Although a great deal is known about the chronic phase of human Chagas' disease, much less is well defined regarding the acute phase of the disease. In this review, the authors discuss (i) the current status of acute Chagas' disease worldwide, (ii) the patient immune response and its impact on disease outcomes, and (iii) the **reactivation of disease in immunocompromised individuals (particularly relevant for organ transplantation recipients and the treatment of patients with HIV infection).** This review includes updates on oral infection (contaminated fruit and fruit juices), congenital infections, blood transfusions and solid organ transplantation, potential problems with diagnosis of acute infections, immune responses in the murine model, the importance of cytokines, and reactivation of disease in immunocompromised patients.

Tenney TD, Curtis-Robles R, Snowden KF, Hamer SA. 2014. Shelter dogs as sentinels for *Trypanosoma cruzi* transmission across Texas. *Emerg Infect Dis* **20:**1323–1326.

Chagas' disease, an infection caused by *Trypanosoma cruzi*, has recently been diagnosed in humans in the southern United States. This infection is now endemic in a number of the southern states. The vectors are also found in many areas throughout the United States. **The authors evaluated exposure of shelter dogs in Texas to *T. cruzi*. They also determined that seroprevalence data for a number of different regions was 8.8%,** a figure that may actually be a low estimate. Serosurveillance of various canine populations has become a helpful mechanism for assessing public health risks associated with this infection. **It is important for health care workers to become more aware of the vectors (kissing bugs, triatomid bugs) of *T. cruzi* and their ecologic niches, as well as the potential risks associated with Chagas' disease in areas where seropositive dogs have been confirmed. Also, it is unknown whether dogs serve as reservoir hosts for *T. cruzi* in the United States; certainly, this has been confirmed from some areas in Central and South America.**

Kransdorf EP, Zakowski PC, Kobashigawa JA. 2014. Chagas disease in solid organ and heart transplantation. *Curr Opin Infect Dis* **27:**418–424.

Diagnosis and management of infections with *Trypanosoma cruzi*, the cause of Chagas' disease, have become much more important in solid organ transplantation patients. This is particularly true in cardiac transplant patients who are at much greater risk of complications than with liver or kidney transplantation. Each year, approximately 2% of infected individuals will progress to Chagas cardiomyopathy. For these transplant patients, comprehensive monitoring for possible disease reactivation is critical for a good clinical outcome. Molecular testing of peripheral blood is more sensitive and much more likely to detect a reactivation process before symptoms are evident. **Transplant teams should implement thorough surveillance protocols for the detection of disease reactivation in both donors and recipients. Although Chagas' disease may seem unusual and infrequent, it is becoming more prevalent in many parts of the world, including the United States.**

Garza M, Feria Arroyo TP, Casillas EA, Sanchez-Cordero V, Rivaldi CL, Sarkar S. 2014. Projected future distributions of vectors of *Trypanosoma cruzi* in North America under climate change scenarios. *PLoS Negl Trop Dis* **8:**e2818. doi:10.1371/journal.pntd.0002818.

Trypanosoma cruzi is transmitted by insects of the family *Reduviidae*, subfamily *Triatominae* (kissing bugs, triatomid bugs). The infection is known as Chagas' disease, which kills around 45 thousand people each year and impacts 10 million people in Latin America and the southern United States. It has been estimated that 300,000 infected people are present throughout Canada and the United States. Epidemiologists predict climate change will influence overall vector distribution, which in turn will alter the overall potential risk of human Chagas' disease. **It has been well documented that vector habitat in the United States continues to expand northward. The authors predict a continued northern shift in the territory of *Trypanosoma gerstaeckeri* and a northern and southern territory shift of *Trypanosoma sanguisuga* due to climate change.**

Martin DL, Goodhew B, Czaicki N, Foster K, Rajbhandary S, Hunter S, Brubaker SA. 2014. *Trypanosoma cruzi* survival following cold storage: possible implications for tissue banking. *PLoS One* **9:**e95398. doi:10.1371/journal.pone.0095398.

Trypanosoma cruzi, the agent of Chagas' disease, can be transmitted via insect vectors, solid organ transplantation, or transfusion of contaminated blood or blood products. In transplantation- or transfusion-related cases, transmission of the causative agent depends on storage conditions used to hold human tissues. The authors report on a number of storage parameters that were not successful in killing the organisms. Trypomastigotes survived and remained infective 24 hours in blood held at room temperature; 24 and 48 hours when held at 4°C; in 2/13 cultures held 28 days at 4°C; and in all specimens stored 365 days at −80°C without cryoprotectant. **If one accepts the reported rate of *T. cruzi* infection in U.S. blood donors of 1:27,000, with approximately 30,000 tissue donors each year, it is highly likely that one or two positive tissue donors will be detected.** While a number of techniques are used for blood product and tissue allograft protection from pathogens, much more work is required to clarify parasite survival and potential risk factors related to *T. cruzi*.

Waleckx E, Suarez J, Richards B, Dorn PL. 2014. *Triatoma sanguisuga* blood meals and potential for Chagas disease, Louisiana, USA. *Emerg Infect Dis*. **20:**2141–2143.

This study provides evidence that *Triatoma sanguisuga* represents a threat to both humans and animals in Louisiana, where contact with *Trypanosoma cruzi* has been documented in 55% of bugs checked. Of note is the fact that almost 40% of these bugs had fed on human blood. Although this study provides evidence of frequent vector-human-*T. cruzi* contact in Louisiana, these findings are not consistent throughout the United States. Raccoons and dogs, as well as woodrats, serve as reservoir animals.

Sanchez DR, Traina MI, Hernandez S, Smer AM, Khamag H, Meymandi SK. 2014. Chagas disease awareness among Latin American immigrants living in Los Angeles, California. *Am J Trop Med Hyg* **91:**915–919.

The number of cases of Chagas' disease in the United States has been estimated to be from 150,000 to over 300,000. **While the majority of these cases originated in Latin America, there is a wide range of understanding of this disease among immigrants currently living in Los Angeles.** In a study of 2,677 immigrants who had lived in Latin America for a minimum of 6 months, 62% had actually seen triatomid bugs in Latin America, and 27% reported being bitten at least once a year. However, 82% were totally unaware of Chagas' disease. Those who had at least heard of the disease reported it was not serious (81%). However, on a more positive note, those who were aware of the disease indicated they preferred to be tested and treated. Unfortunately, the data indicated that in this particular group of immigrants, the overall awareness of Chagas' disease was very limited. Another important issue to consider is that this infection is now endemic in many areas of the southern United States; therefore, we expect to see future cases in the population in individuals who have never been outside the United States.

Intestinal Nematodes

Hookworm

Croese J, Giacomin P, Navarro S, Clouston A, McCann L, Dougall A, Ferreira I, Susianto A, O'Rourke P, Howlett M, McCarthy J, Engwerda C, Jones D, Loukas A. 2014. Experimental hookworm infection and gluten microchallenge promote tolerance in celiac disease. *J Allergy Clin Immunol* **135:**508–516.

Celiac disease is a common gluten-sensitive autoimmune disorder of the small intestine that occurs in people who are genetically predisposed. Absorption of nutrients can be severely compromised, villous atrophy is seen, and a gluten-free diet is recommended. However, compliance with this regimen can be very difficult to achieve. Since parasitic helminths have been used for the treatment of inflammatory disorders, the authors assessed the impact of experimental *Necator americanus* infection on celiac disease patients who received increased gluten over time. **The study revealed no decrease in the villous blunting; however, the overall quality of life improved, T cells (IFNy) were reduced, and regulatory T cells increased. Overall, this approach maintained or improved gluten toxicity indicators in this patient group.**

Strongyloides stercoralis

Puthiyakunnon S, Boddu S, Li Y, Zhou X, Wang C, Li J, Chen X. 2014. Strongyloidiasis: an insight into its global prevalence and management. *PLoS Negl Trop Dis* **8:**e3018. doi:10.1371/journal.pntd.0003018.

Strongyloides stercoralis infects more than 100 million people worldwide. *Strongyloides* have a free-living stage within the life cycle, as well as an autoinfective cycle. Patient presentations vary from those who are asymptomatic to those with the fatal hyperinfection or disseminated infection syndromes. **Important risk factors include immunosuppression related to corticosteroid use, infection with human T-lymphotropic virus or human immunodeficiency virus, hematology malignancies, and allograft transplant recipients.** Strongyloidiasis is classified as one of the neglected tropical diseases. Diagnostic procedures tend to miss the infection (low parasitemia), and the infection may not be suspected (nonspecific clinical symptoms). Improved molecular methods and a more comprehensive understanding of this infection are critical for good clinical outcomes.

Salvador F, Sulleiro E, Sánchez-Montalvá A, Saugar JM, Rodríguez E, Pahissa A, Molina I. 2014. Usefulness of *Strongyloides stercoralis* serology in the management of patients with eosinophilia. *Am J Trop Med Hyg* **90:**830–834.

It is important to remember that *Strongyloides stercoralis* infections continue to be seen in areas of no endemicity. Use of the *S. stercoralis* serology in patients presenting with eosinophilia has become more widely recommended. In this study 147 patients were involved; 28 had HIV, and 89 (60.5%) patients had a positive *S. stercoralis* serology. However, using diagnostic tests that are somewhat insensitive, larvae were detected only in 15 (10.2%) patients. Eighty patients were given ivermectin 200 μg/kg/day for 2 days; 32 patients were seen for follow-up after 6 months. Twenty-six patients (81.3%) had a negative serology 6 months after treatment. Also, the EIA posttreatment to pretreatment decreased to 0.6, and 11 (34.4%). Based on this and other published data, ***S. stercoralis* serology is valuable in supporting the presumptive diagnosis and for subsequent testing post-therapy.**

Anatrichosoma spp.

Eberhard ML, Hellstein JW, Lanzel EA. 2014. Zoonotic anatrichosomiasis in a mother and daughter. *J Clin Microbiol* **52:**3127–3129.

Human infections with *Anatrichosomia* spp. (small tichuroid nematodes) are rare and are usually associated with oral lesions. The complete life cycle remains unknown, although it may include an arthropod intermediate host. This case reports infection in a mother and daughter. Both patients were seen after a 10-week history of multiple painful oral ulcers. Biopsy tissue examination showed small, coiled trichuroid nematodes with morphological features compatible with *Anatrichosoma* spp. Morphology revealed stichocytes, which were visible in the anterior end, a small tubular esophagus, and the presence of two bacillary bands. In a previous case reported by these authors, the patient was treated with 100 mg mebendazole twice daily for 20 days; this therapy was successful.

Tissue Nematodes

Angiostrongylus cantonensis

York EM, Butler CJ, Lord WD. 2014. Global decline in suitable habitat for *Angiostrongylus* (= *Parastrongylus*) *cantonensis*: the role of climate change. *PLoS One* **9:**e103831. doi:10.1371/journal.pone.0103831.

The parasite *Angiostrongylus* (= *Parastrongylus*) *cantonensis* is an invasive helminth that causes eosinophilic meningitis in humans. *A. cantonensis* has been reported from more than 30 countries worldwide. Given the health risks and serious disease sequelae, it is important to identify habitats where climate currently supports *A. cantonensis* or those in which these parasites could become established in the future. Although some evidence from this study indicates an overall decline in suitable habitats, these results do not agree with other published studies. Overall evidence suggests that the prevalence of parasitic pathogens will continue to increase throughout this century. **Based on this evidence, *A. cantonensis* will most likely continue to expand its geographic range; however, overall climate change may reduce the total geographic area of suitable climatic conditions throughout the 21st century.**

Stockdale-Walden HD, Slapcinsky J, Qvarnstrom Y, McIntosh A, Bishop HS, Rosseland B. 2015. *Angiostrongylus cantonensis* in introduced gastropods in southern Florida. *J Parasitol* **101:**156–159.

This infection has been reported throughout the world in many countries and is prevalent in Asia, the Pacific Islands, and the Caribbean. Human infection begins with the accidental ingestion of infective larvae in several species of slugs, snails, or land planarians. Ingestion of infected raw paratenic hosts, including fish, amphibians, reptiles, crustaceans, and vegetables contaminated with larvae, also leads to infection of the human host. In the natural life cycle, infective larvae have also been found in land crabs, coconut crabs, and freshwater prawns, which are often consumed raw in the Pacific Islands. In summary, human infection can originate through the following: ingestion of L3 larvae in raw or undercooked intermediate or paratenic hosts, drinking infected water, oral contact with hands contaminated with mollusk larvae, or possibly through the skin. There are three major forms of human angiostrongyliasis: meningitic, encephalitic, and ocular; the majority of patients exhibit the meningitic form. Although rare, the infection can be fatal. Symptoms include severe headache, convulsions, weakness of the limbs, paresthesia, vomiting, constipation, nausea, anorexia, facial paralysis, neck stiffness, and fever. **The presence of definitive and intermediate hosts strongly suggests the presence of *A. cantonensis* in south Florida.**

Anisakiasis

Baird FJ, Gasser RB, Jabbar A, Lopata AL. 2014. Foodborne anisakiasis and allergy. *Mol Cell Probes* **28:**167–174.

Anisakiasis in humans is a disease caused by *Anisakis* spp. (*Nematoda*) and often presents as acute gastroenteritis, which is the most commonly recognized clinical syndrome and which mimics bacterial or viral gastroenteritis. Since the presence of anisakid larvae in infected marine fish is worldwide, the risk of anisakiasis in developed countries is probably under-recognized and underreported. **This disease not only causes serious symptoms in the gastrointestinal tract, but it is well documented that these infections can also cause serious allergic reactions in patients who have become sensitized.** Allergic symptoms range from urticaria and isolated angioedema to anaphylaxis. It has been highly recommended that serologic testing for antibody to *Anisakis* spp. should be performed on any patient where the presumptive diagnosis is eosinophilic gastroenteritis.

Baylisascaris procyonis

Page K, Smyser TJ, Dunkerton E, Gavard E, Larkin B, Gehrt S. 2014. Reduction of *Baylisascaris procyonis* eggs in raccoon latrines, suburban Chicago, Illinois, USA. *Emerg Infect Dis* **20:**2137–2140.

Baylisascaris procyonis is the raccoon ascarid, has a normal ascarid-like life cycle, causes a very serious zoonotic disease in humans (larval migrans), and is most often reported in North America. Adult worms produce 150,000 eggs/worm/day, and infected raccoons can shed as many as 250,000 eggs per gram of feces. This level of egg production can lead to significant environmental contamination of the soil, particularly in areas where the raccoons defecate (raccoon latrines). Although many control measures have been tried, most have proven to be unsuccessful. **However, this study reports on the success of an antihelmintic baiting approach for the reduction of environmental contamination with *B. procyonis* eggs.**

Capillaria hepatica (*Calodium hepaticum*)

Fuehrer HP. 2014. An overview of the host spectrum and distribution of *Calodium hepaticum* (syn. *Capillaria hepatica*). Part 2. *Mammalia* (excluding *Muroidea*). *Parasitol Res* **113:**641–651.

Calodium hepaticum (syn. *Capillaria hepatica*) is a zoonotic nematode found worldwide with low host specificity; it is found in

25 families of nonrodent mammals and is primarily found in the liver. Various animal groups involved are the *Insectivora*, *Chiroptera*, *Lagomorpha*, *Artiodactyla*, *Perissodactyla*, *Hyracoidea*, *Marsupialia*, *Carnivora*, and *Primates*, including humans. There is a direct life cycle, which includes egg ingestion, hatching within the cecum, and liver invasion via the portal veins. Adult worms remain in the liver for up to 60 days. Egg ingestion of infected animal livers results in spurious infections, and eggs are passed in the feces. **Diagnosis is primarily based on liver biopsy and autopsies; because the eggs of this helminth can be easily confused with those of other genera/species, infection reports may be somewhat inaccurate.**

Gnathostoma spp.

Cole RA, Choudhury A, Nico LG, Griffin KM. 2014. *Gnathostoma spinigerum* in live Asian swamp eels (*Monopterus* spp.) from food markets and wild populations, United States. *Emerg Infect Dis* **20:**634–642.

In various areas within Asia, wild and aquaculture-grown swamp eels (*Synbranchidae*: *Monopterus* spp.) are a common food source for humans, a practice which leads to gnathastomiasis. Live Asian swamp eels are imported to U.S. markets, and populations in the wild are documented in several states. The authors examined 47 eels from markets and 67 wild-caught specimens for the presence of *Gnathostoma*. Thirteen (27.7%) *Monopterus cuchia* eels from markets were infected with 36 live *Gnathostoma spinigerum* AL3: most (21) were in the liver (58.3%), 7 (19.4%) in muscle, 5 (13.8%) in the gastrointestinal tract, and 3 (8.3%) in kidneys. Species from North America included three (4.5%) wild-caught *Monopterus albus* eels that were infected with five *Gnathostoma turgidum* AL3 in muscle, and one *Gnathostoma lamothei* AL3 that was found in a kidney. In U.S. ethnic food markets, imported swamp eels from Asia and native and nonnative fishes are commonly maintained alive for purchase. Often, customers will ask to have the fish processed before they leave the market. It is also known that some of these fish are released into the wild, thus potentially introducing nonendemic parasites into native habitats.

Toxocara spp.

Lee RM, Moore LB, Bottazzi ME, Hotez PJ. 2014. Toxocariasis in North America: a systematic review. *PLoS Negl Trop Dis* **8:**e3116. doi:10.1371/journal.pntd.0003116.

Toxocariasis is an important neglected tropical disease caused by *Toxocara canis* and *Toxocara cati* that can be seen in humans as visceral or ocular larva migrans or as asymptomatic disease. This infection is of public health concern, and illness can cause serious sequelae. The authors conducted a systematic PubMed review of the literature to determine the disease prevalence in North America. They reviewed 18 articles with original prevalence, incidence, or case data for toxocariasis. Prevalence estimates ranged from a low of 0.6% in a Canadian Inuit community to a high of 30.8% in Mexican children presenting with asthma. Risk factors have been identified as African-American race, poverty, male sex, age under 18, living in the southern United States, and dog or cat ownership or children playing in uncovered sandboxes where animals tend to defecate. This disease is definitely considered in "no pet beaches" where sand, sun, and moisture provide an excellent environment for these nematodes. Additional studies from Mexico have identified other high-risk groups including waste pickers, asthmatic children, and inpatient psychiatry patients. Although a thorough understanding of these infections remains incomplete, they produce very serious sequelae, particularly in young children.

Trichinella spp.

Hill DE, Dubey JP, Baroch JA, Swafford SR, Fournet VF, Hawkins-Cooper D, Pyburn DG, Schmit BS, Gamble HR, Pedersen K, Ferreira LR, Verma SK, Ying Y, Kwok OC, Feidas H, Theodoropoulos G. 2014. Surveillance of feral swine for *Trichinella* spp. and *Toxoplasma gondii* in the USA and host-related factors associated with infection. *Vet Parasitol* **205:**653–665.

Trichinella spp. and *Toxoplasma gondii* are found worldwide and are significant zoonotic parasites that tend to infect warm-blooded animals and humans. While pigs are the main host for *Trichinella spiralis*, many animals such as pigs, chickens, sheep, and goats can be infected with *T. gondii*. It has been documented that wildlife infections have a higher incidence than those seen in domestic animals. Feral swine are reservoirs in the sylvatic habitat for *Trichinella* spp. and *T. gondii* and are infection sources for carnivores that are found within the same areas as domestic pigs. Feral swine in direct contact with domestic pigs can lead to infection through cannibalism.

Between 2006 and 2010, the authors conducted a serological survey in the United States to obtain estimates regarding *Trichinella* spp. and *T. gondii* and potential infection risk factors for feral swine. Serum samples (3,247) were tested, and results are available from 26 states. Seroprevalence data were 3.0% for *Trichinella* spp. and 17.7% for *T. gondii*. Distribution areas for both parasites were similar and tended to concentrate in the South and the Midwest. A subsequent survey of 984 feral pigs between 2012 and 2013 revealed a 2.9% rate for *Trichinella* spp. and 28.4% for *T. gondii*. Tongues (330) were sampled from the 984 animals, and 1.81% of the feral pigs were confirmed positive for *T. spiralis*. **With the potential for overlapping feral pig and domestic pig habitat/production facilities, it is quite possible that *Trichinella* spp. and *T. gondii* could be introduced into domestic pigs in the United States.**

Filarial Nematodes

Paniz-Mondolfi AE, Gárate T, Stavropoulos C, Fan W, González LM, Eberhard M, Kimmelstiel F, Sordillo EM. 2014. Zoonotic filariasis caused by novel *Brugia* sp. nematode, United States, 2011 [letter]. *Emerg Infect Dis* **20:**1248–1250.

Brugia spp. filarial worms that normally infect nonhuman vertebrates have been identified as rarely causing human zoonotic infection. **While lymphatic filariasis caused by *Brugia malayi* and *Brugia timori* occurs in Asia, most zoonotic infections with other**

animal species of *Brugia* are documented from the northeastern United States or South America. One case report occurred in a New York City resident with no relevant travel history. This patient suffered from right groin swelling and had a 12% eosinophilia, and the biopsy revealed intralymphatic nematodes with living microfilariae. Subsequently, the patient complained of inguinal swelling; on repeat biopsy no additional worms were detected. However, the patient was given oral doxycycline for 6 weeks, followed by ivermectin and albendazole, with no further problems for over 2 years. Since many reported patient infections are asymptomatic or confirmed as incidental findings, the overall disease prevalence remains undetermined. Also, in areas of disease endemicity, cases are unlikely to be categorized as zoonotic or conventional. The majority of cases were reported from the Northeast, including New York (eight), Massachusetts, Pennsylvania, Connecticut, and Rhode Island (three); single cases have been identified in Michigan, Ohio, North Carolina, Oklahoma, New Jersey, Louisiana, Florida, and California. Outside of the United States, three cases have been reported from South America (Colombia, Brazil, Peru) and one from Africa (Ethiopia). *Brugia leporis* is seen in rabbits in the northeastern United States, *Brugia beaveri* is found in raccoons and bobcats in the southern United States, and *Brugia guyanensis* is found in the coatimundi and other vertebrates in South America.

Hopkins DR, Ruiz-Tibin E, Eberhard ML, Roy SL. 2014. Progress toward global eradication of dracunculiasis: January 2013-June 2014. *MMWR Morb Mortal Wkly Rep* **63:**1050–1054.

The number of new cases of dracunculiasis (Guinea worm disease) worldwide each year has decreased from an estimated 3.5 million in 1986 (the year global elimination as a goal was announced) to 148 in 2013. The number of cases worldwide in 2013 (148) declined by 73% compared with 2012 (542), and by 71% during January–June 2014 (27) compared with January–June 2013 (92). Transmission remains endemic in four countries (Mali, Chad, Ethiopia, Sudan), with South Sudan accounting for 70% of all reported cases during January–June 2014. Although the original eradication dates were missed, it is anticipated that eradication is likely during the next year or two.

Mombo-Ngoma G, Mackanga JR, Basra A, Capan M, Manego RZ, Adegnika AA, Lötsch F, Yazdanbakhsh M, Gonzalez R, Menendez C, Mabika B, Matsiegui PB, Kremsner PG, Ramharter M. 2015. *Loa loa* infection in pregnant women, Gabon. *Emerg Infect Dis* **21:**899–901.

A prospective study of pregnant women in Central Africa revealed a high prevalence of *Loa loa* infection. Although little information is available on the epidemiology of this infection in pregnancy, **the invasion of microfilariae into the intervillous space of the placenta was confirmed in this study**. Additional clinical studies are under way to clarify these findings.

Hassan KH, Bolcen S, Kubofcik J, Nutman TB, Eberhard ML, Middleton K, Wekesa JW, Ruedas G, Nelson KJ, Dubielzig R, De Lombaert M, Silverman B, Schorling JJ, Adler PH, Unnasch TR, Beeler ES. 2015. Isolation of *Onchocerca lupi* in dogs and black flies, California, USA. *Emerg Infect Dis* **21:**789–796.

Data from this study confirm that canine infections with *Onchocerca lupi* are ongoing in California; thus, cats and humans could also be potentially infected. It has been suggested that other canids such as coyotes could serve as reservoir animals. **Although it is unknown whether common heartworm medications used for dogs are effective against the larvae of *O. lupi*, their use may help prevent infection in pets.**

Otranto D, Giannelli A, Latrofa MS, Dantas-Torres F, Trumble NS, Chavkin M, Kennard G, Eberhard ML, Bowman DD. 2015. Canine infections with *Onchocerca lupi* nematodes, United States, 2011-2014. *Emerg Infect Dis* **21:**868–871.

Since canine onchocerciasis caused by *Onchocerca lupi* has been documented in Arizona, California, Colorado, Florida, Minnesota, New Mexico, and Utah, it has been recommended that further studies be expanded throughout the United States. **The potential for dogs to serve as reservoir hosts for possible human infections has taken on more importance as additional canine and human cases are reported.**

Intestinal Cestodes

Taenia saginata

Tembo A, Craig PS. 2014. *Taenia saginata* taeniosis: copro-antigen time-course in a voluntary self-infection. *J Helminthol* **19:**1–8.

Although infection with *Taenia saginata* is worldwide where beef is consumed, relatively little is known about the early stage in humans. While copro-antigen detection is helpful in patient screening for *T. solium*, there are essentially no data related to early *T. saginata* infection. A self-infection with *T. saginata* was initiated and monitored for 6 months using a copro-antigen enzyme-linked immunosorbent assay (ELISA) developed by the authors. The first proglottid was seen on day 86 postinfection and was followed by almost daily release of proglottids (range 1–8) until praziquantel therapy on day 180 postinfection. For the first 10 weeks the patient remained asymptomatic. By weeks 15–19 postinfection, abdominal discomfort was the main clinical finding, while involuntary proglottid discharge continued during the infection period. Copro-antigens were detected 2 weeks before proglottids were detected, remained highly elevated until treatment, and reverted to negative 4 days posttherapy. **Although copro-antigen ELISA is an appropriate and sensitive diagnostic test in *T. saginata* infections with gravid worms, it is much less sensitive prior to the release of proglottids.**

Taenia solium

**O'Neal SE, Moyano LM, Ayvar V, Rodriguez S, Gavidia C, Wilkins PP, Gilman RH, Garcia HH, Gonzalez AE, Cysticercosis

Working Group in Peru. 2014. Ring-screening to control endemic transmission of *Taenia solium*. *PLoS Negl Trop Dis*. **8**:e3125. doi:10.1371/journal.pntd.0003125.

In many areas of the world, including Latin America, Asia, and Africa, *Taenia solium* is the third leading cause of preventable epilepsy. Elimination of infection with the adult tapeworms would help reduce exposure to the infective eggs (cause of human/pig cysticercosis). The authors implemented a detection/therapy program among household personnel (1,058 in the study site, 753 in the control site) located in a defined radius around heavily infected pigs (ring screening) (1,444 from the study site, 966 from the control site). After 1 year, including therapy for confirmed human cases with adult *T. solium*, the authors documented a 41% reduction in seroprevalence in the study site, while the control site remained the same. **Although this screening approach was very effective, empiric therapy using niclosamide for humans and oxfendazole for pigs remains another option based on drug safety records.**

Garcia HH, Gonzales I, Lescano AG, Bustos JA, Pretell EJ, Saavedra H, Nash TE, Cysticercosis Working Group in Peru. 2014. Enhanced steroid dosing reduces seizures during antiparasitic treatment for cysticercosis and early after. *Epilepsia* **55**:1452–1459.

Neurocysticercosis is one of the leading causes of seizures and epilepsy in areas worldwide where *Taenia solium* is endemic. In some countries the prevalence exceeds 10%, and neurocysticercosis is responsible for up to 50% of late-onset epilepsy cases. Patient responses vary from being asymptomatic with overall parasite tolerance to a severe inflammatory response. Antiparasitic therapy and subsequent death of the organisms may lead to serious inflammatory reactions by the patient. In many cases, steroids are given at the same time to avoid these inflammatory complications. The authors made the assumption that increased steroid dosing would decrease treatment-associated seizures in neurocysticercosis patients. **Data confirmed that dexamethasone resulted in fewer seizures for the first 21 days during and early after antiparasitic treatment with albendazole; however, this finding was not consistent during the first 11–42 days, which was the preset primary selected time frame for the study outcome assessment of seizure days and patients with seizures.**

Cantey PT, Coyle CM, Sorvillo FJ, Wilkins PP, Starr MC, Nash TE. 2014. Neglected parasitic infections in the United States: cysticercosis. *Am J Trop Med Hyg* **90**:805–809.

The larval forms of *Taenia solium* are called cysticerci; they have been recovered from all areas of the human body, produce symptoms that depend on the particular body site involved, and can cause fatal disease. The presence of cysticerci in the brain represents the most frequent parasitic infection of the human nervous system and the most common cause of adult-onset epilepsy throughout the world. Patients with neurocysticercosis may have seizures or increased intracranial pressure. Although many emigrants in the United States came from cysticercosis-endemic areas such as Mexico and Latin America and autochthonous transmission has been documented in the United States, information regarding the disease epidemiology in this country is limited. A number of things are recommended, including mandatory reporting, the determination of better prevalence/hospitalization data, development of prospective data on mortality risks, improved diagnostic testing, and clarification of treatment and patient management recommendations.

O'Keefe KA, Eberhard ML, Shafir SC, Wilkins P, Ash LR, Sorvillo FJ. 2014. Cysticercosis-related hospitalizations in the United States, 1998-2011. *Am J Trop Med Hyg* **92**:354–359.

The authors reviewed inpatient records for cysticercosis using the Nationwide Inpatient Sample for 1998–2011. There were 33,060 cysticercosis-related hospitalizations during this time frame (8.03/million). Key statistics included male (54.8%), Hispanic (62.0%), age 18–44 (58.8%), occurred in the western U.S. (45.1%), and deaths (459; fatality rate of 1.4%). The authors recommend that cysticercosis should be a nationally reportable disease, and the overall numbers are greater than previously thought.

Del Brutto OH, Salgado P, Lama J, Del Brutto VJ, Campos X, Zambrano M, Garcia HH. 2015. Calcified neurocysticercosis associates with hippocampal atrophy: a population-based study. *Am J Trop Med Hyg* **92**:64–68.

Although calcified cysticerci in the brain parenchyma in many cases have been considered clinically insignificant, in areas of endemicity there may be large numbers of patients with **epilepsy and neurocysticercosis**. There has also been a link between calcified cysticerci and **hippocampal atrophy**. In a recent study of patients (≥60) in Ecuador, there was a definite association between calcified cysticerci and hippocampal atrophy. Subsequent studies are being planned for younger individuals to determine (i) if calcified cysticerci are related to the development of hippocampal atrophy over time and (ii) whether hippocampal atrophy is linked to temporal lobe epilepsy.

Tissue Cestodes

Echinococcus spp.

Rogan MT, Bodell AJ, Craig PS. 2014. Post-encystment/established immunity in cystic echinococcosis: is it really that simple? *Parasite Immunol* **37**:1–9.

Although multiple studies have investigated immunity to larval cestodes, clarification of a two-phase system is probably too simplistic. *Echinococcus* spp. exhibit different developmental changes depending on the host and include growth, regeneration, and deterioration. Cyst classification based on clinical grounds is undergoing change. **Based on medical and veterinary information, the authors have proposed that the "established" phase for *Echinococcus granulosus* could be further divided into the following phases: maturing, stable, unstable, and degenerative.**

Martel G, Ismail S, Begin A, Vandenbroucke-Menu F, Lapointe R. 2014. Surgical management of symptomatic hydatid liver disease: experience from a Western centre. *Can J Surg* **57:**320–326.

The majority of hydatid cysts occur in the liver, primarily in the right lobe. Symptoms include chronic abdominal discomfort, occasionally with a palpable or visible abdominal mass, pain, hepatomegaly, cholestasis, biliary cirrhosis, portal hypertension, and ascites. Treatment options for hydatid disease include medical treatment with albendazole or mebendazole for smaller cysts, conservative surgery (drainage, some tissue removal, cavity management), and radical surgery (liver resection). Based on World Health Organization recommendations, "surgery was [the] recommendation for large liver cysts; symptomatic cysts; cysts at risk of rupture; infected cysts; and cysts demonstrating or at risk for developing fistulas into the biliary tree, diaphragm/pleural cavity or other vital organs." The authors reported that 67% of patients received drugs prior to surgery, 87% after surgery, and 60% pre- and postsurgery. Eighty-three percent underwent liver resection, while 18% underwent conservative therapy. **Study data reinforced the fact that liver surgery for echinococcosis in North America is somewhat rare; however, the data also documented a large number of complicated cysts in terms of clinical management.** This publication provides an excellent discussion of the pros and cons of hydatid cyst management in North America.

Piccoli L, Tamarozzi F, Cattaneo F, Mariconti M, Filice C, Bruno A, Brunetti E. 2014. Long-term sonographic and serological follow-up of inactive echinococcal cysts of the liver: hints for a "watch-and-wait" approach. *PLoS Negl Trop Dis* **8:**e3057. doi:10.1371/journal.pntd.0003057.

Cystic echinococcosis is one of the neglected parasitic diseases and can have a wide range of presentations in terms of involved organs, varying cyst stages, and patient clinical symptoms, from those who are asymptomatic to those with severe sequelae. Although radical surgery, minor surgery, and chemotherapy (with or without surgical intervention) are the three approaches to treatment, extensive evaluation of these approaches has been lacking. **With the advent of ultrasound options, those with experience in treating echinococcosis have recommended that uncomplicated inactive cysts should be monitored but not treated.** The authors report that over a 19-year period, 97.4% of their patients with inactive cysts were monitored for 2 years with no evidence of reactivation. Their data were also confirmatory in suggesting that serologic testing was helpful but could not be used alone to guide the clinical management of these patients.

Grenouillet F, Umhang G, Arbez-Gindre F, Mantion G, Delabrousse E, Millon L, Boué F. 2014. *Echinococcus ortleppi* infections in humans and cattle, France. *Emerg Infect Dis* **20:**2100–2102.

Echinococcus orleppi has a dog-cattle cycle with limited pathogenicity for human infections (eight reported cases previously). Although most reports originate from South America, limited reports have come from other locations. Recently, human and cattle infections have been reported from France. **Because most diagnostic reagents are prepared from *Echinococcus granulosus*, negative results in patients with *Echinococcus orleppi* may result in underreporting of this infection.**

Stijnis K, Dijkmans AC, Bart A, Brosens LAAS, Muntau B, Schoen C, Barth TF, van Gulik T, van Gool T, Grobusch MP, Tappe D. 2015. *Echinococcus vogeli* in immigrant from Suriname to the Netherlands. *Emerg Infect Dis* **21:**528–530.

It is known that echinococcosis infections (polycystic *Echinococcus vogeli*, unicystic *Echinococcus oligarthrus*) have been confirmed as emerging infections in South America, primarily Brazil. The life cycle of *E. vogeli* includes the intermediate host (pacas) and the final host (bush dogs). A recent case has been identified in a patient seen in the Netherlands. The patient was a 48-year-old female who presented for retrosternal pain; she had immigrated to the Netherlands from Suriname approximately 20 years before. Although most physical and laboratory findings were reported as normal, abdominal ultrasonography demonstrated a mixed solid/liquid lesion that suggested a biliary cystadenoma or an echinococcal cyst. The patient's serology was strongly positive; subsequently, surgical resection was performed, resulting in removal of an 8-cm polycystic tumor. While the original diagnosis was suggestive of *Echinococcus multilocularis* or *Echinococcus granulosus*, further examination using PCR revealed 99 to 100% homology with *E. vogeli*. **This and other cases indicate that there may be more undiagnosed cases of *E. vogeli* in immigrants from South America. Based on a presumptive diagnosis, these patients would receive preoperative and long-term therapy with albendazole.** Excellent images of rostellar hooks from the protoscolices can be found in the same issue of the journal on page 458 ("*Polycystis echinococcosis* in pacas, Amazon region, Peru").

Spirometra spp.

Cheng KB, Gao BL, Liu JM, Xu JF. 2014. Pulmonary sparganosis mansoni: a case report from a nonendemic region. *J Thorac Dis* **6:**E120–E124.

The larval forms (spargana) of *Spirometra mansonoides* can be found in the subcutaneous connective tissue and between the muscles in frogs, lizards, snakes, birds, and certain mammals. Sparganosis is most common in China, Japan, and Southeast Asia. This case involved a 32-year-old female who had no relevant travel history and who was misdiagnosed as having eosinophilic pneumonia. Although she was treated for approximately 2 months with corticosteroids, she remained symptomatic. Her computed tomography scan demonstrated lesions, and she was admitted for additional workups. Per her medical history, she commonly ate raw seafood, as well as various types of raw frogs. A serologic result revealed antibodies consistent with the diagnosis of pulmonary sparganosis, and she was successfully treated with praziquantel. **Although this infection is rare, a thorough medical history is required to diagnose sparganosis in either endemic or nonendemic areas where the patient has a history of ingesting raw frogs or snakes.**

Lung Trematodes

Paragonimus spp.

Xia Y, Ju Y, Chen J, You C. 2014. Hemorrhagic stroke and cerebral paragonimiasis. *Stroke* **45:**3420–3422.

Hemorrhagic cerebral paragonimiasis patients (10) were reviewed for clinical findings, diagnosis, and therapy. Patients underwent various diagnostic procedures including brain computed tomography scans (10), magnetic resonance imaging (9), computed tomography angiography (4), magnetic resonance angiography (4), digital subtraction angiography (4), cerebrospinal fluid cytology examination (7), and follow-up (9) for 12 to 62 months. In reviewing 27 cerebral paragonimiasis cases overall, 10/27 (37%) had hemorrhagic complications. As would be expected, symptoms included severe headaches, blurred vision, tinnitus, vomiting, hemiparalysis, and epilepsy. While four cases underwent surgery and symptoms improved, central nervous system deficits remained in three of these patients. **With cerebral paragonimiasis, it is imperative that treatment be initiated as quickly as possible to decrease the risk of stroke complications.**

Song J, Hong G, Song JU, Kim W, Han SG, Ko Y, Chang B, Jeong BH, Eom JS, Lee JH, Jhun BW, Jeon K, Kim HK, Koh WJ. 2014. A case of pleural paragonimiasis confused with tuberculous pleurisy. *Tuberc Respir Dis (Seoul)* **76:**175–178.

Paragonimus westermani causes pleuropulmonary disease in humans. Symptoms can often mimic other disorders such as tuberculosis or cancer. The patient was a 38-year-old man with pleural effusion (radiography) with pleural thickening (computed tomography scan). Prior to the computed tomography scans, the patient was seen after the development of a right pneumothorax; based on a chest radiograph and other clinical findings, he was started on empirical therapy for tuberculosis (isoniazid, rifampin, ethambutol, pyrazinamide). After continued failure to improve, surgery was performed, and pathology findings included granulomatous inflammation with helminth eggs. Prior therapy was withdrawn, and the patient was started on praziquantel. After posttherapy and follow-up (2 years), the patient remains symptom free. **In areas where tuberculosis and paragonimiasis are endemic, it is important to consider pleural paragonimiasis as a potential diagnosis in patients with pleural effusion.**

Blood Trematodes (Schistosomes)

Scott PL, Lim RM, Dukes JP, Cook RT, Walker AJ, Kirk RS. 2014. Identification of a major causative agent of human cercarial dermatitis, *Trichobilharzia franki* (Müller and Kimmig 1994), in southern England and its evolutionary relationships with other European populations. *Parasit Vectors* **7:**277.

Many species of bird schistosomes have been documented to cause human cercarial dermatitis (CD). These schistosomes are seen worldwide, and CD is thought to be an emerging infectious disease, either through the spread of areas of endemicity and/or in more accurate recognition of the disease. CD follows skin penetration by cercariae released from freshwater snail intermediate hosts, and the allergic reaction may be due partly to previous host exposure. Few symptoms are associated with primary exposure, but both humoral and cellular immune responses are elicited on subsequent exposure. After cercarial skin penetration, petechial hemorrhages with edema and pruritus occur. The subsequent maculopapular rash, which may become vesicular, may last 36 h or more. Dermatitis is a constant feature of human infection with avian schistosomes, with cercarial death occurring in the subcutaneous tissues and immediate hypersensitivity reactions occurring at the invasion sites. *Trichobilharzia* spp. are the most common cause of CD and have been confirmed in outbreaks in the United States and Europe. Based on molecular testing, *Trichobilharzia franki* was identified in the United Kingdom, and these isolates were closely related to populations from France. CD must be included in the list of differential diagnosis of skin lesions, especially in areas of endemicity where migratory waterfowl influence potential habitats.

El Scheich T, Holtfreter MC, Ekamp H, Singh DD, Mota R, Hatz C, Richter J. 2014. The WHO ultrasonography protocol for assessing hepatic morbidity due to *Schistosoma mansoni*. Acceptance and evolution over 12 years. *Parasitol Res* **113:**3915–3925.

This study reviews the worldwide acceptance of the World Health Organization (WHO) ultrasound protocol for the evaluation of hepatosplenic disease due to *Schistosoma mansoni* published in 2000. Sixty studies involving 37,424 patients from 15 countries were included in the study. Use of the WHO procedure increased from 43.75% during 2001 to 2004 to 84.61% in 2009 to 2012. Results using the pictorial image approach are reported in 38 of 41 reviewed publications, measurements of portal branch walls were reported in 19 of 41, and results are reported in 2 of 41. The practical usefulness of the pictorial approach of the WHO protocol is confirmed by its wide acceptance. **The WHO pictorial approach has gained wide acceptance based on reproducibility, evaluation of pathology, and comparisons between different locations.**

Doumbo S, Tran TM, Sangala J, Li S, Doumtabe D, Kone Y, Traoré A, Bathily A, Sogoba N, Coulibaly ME, Huang CY, Ongoiba A, Kayentao K, Diallo M, Dramane Z, Nutman TB, Crompton PD, Doumbo O, Traore B. 2014. Coinfection of long-term carriers of *Plasmodium falciparum* with *Schistosoma haematobium* enhances protection from febrile malaria: a prospective cohort study in Mali. *PLoS Negl Trop Dis* **8:**e3154. doi:10.1371/journal.pntd.0003154.

The authors evaluated the impact of baseline *Schistosoma haematobium* infection, baseline *Plasmodium falciparum* infection, and coinfection with both organisms on the possible risk of febrile malaria. Patients who were found to be positive for *S. haematobium* were treated within a few weeks with praziquantel. Malaria episodes were tracked for 7 months. After adjustment for a number of factors, baseline *P. falciparum* mono-infection ($n = 254$) and coinfection ($n = 39$) were highly related to protection from febrile malaria. The protective effect of coinfection was greatest in patients with no anemia. Coinfection was also linked with lower parasitemia during the first febrile episode. **This study confirmed that coinfection with *S. haematobium* and *P. falciparum* substantially decreases the risk of febrile malaria in asymptomatic carriers of *P. falciparum*.**

Ross AG, Olveda RM, Chy D, Olveda DU, Li Y, Harn DA, Gray DJ, McManus DP, Tallo V, Chau TN, Williams GM. 2015. Can mass drug administration lead to the sustainable control of schistosomiasis? *J Infect Dis* **211:**283–289.

In the Philippines, the current control approach for schistosomiasis is yearly mass drug administration (MDA) with 40 mg/kg of praziquantel in all areas with a prevalence of ≥10%. Despite schistosomiasis control efforts for over 30 years, including MDA, the mean prevalence of schistosomiasis among 10,435 subjects was 27.1%. High morbidity findings included left-lobe liver enlargement (89.3%), grade II/III liver parenchyma fibrosis (25%), and splenomegaly (13.3%). **MDA alone was unable to control the prevalence, intensity of infection, or morbidity of schistosomiasis.**

Santos J, Gouveia MJ, Vale N, Delgado Mde L, Gonçalves A, da Silva JM, Oliveira C, Xavier P, Gomes P, Santos LL, Lopes C, Barros A, Rinaldi G, Brindley PJ, da Costa JM, Sousa M, Botelho MC. 2014. Urinary estrogen metabolites and self-reported infertility in women infected with *Schistosoma haematobium*. *PLoS One* **9:**e96774. doi:10.1371/journal.pone.0096774.

It is suspected that urogenital schistosomiasis caused by *Schistosoma haematobium* may be the most neglected tropical disease in sub-Saharan Africa, with over 120 million cases caused by this infection. Based on prior studies involving metabolic pathways in cancer caused by estrogens, the authors developed a study of female residents in Angola, where urogenital schistosomiasis is endemic. Women and girls (93) provided data on urinary, urogenital, and gynecological symptoms. Urine was collected for the detection of schistosome eggs, and liquid chromatography diode array detection electron spray ionization mass spectrometry was used to confirm urine estrogen metabolites. **Estrogen-like metabolites thought to originate from schistosomes were confirmed in the urine of *S. haematobium*–positive patients, while negative patients had no similar metabolites. These metabolites were definitely linked to infertility.**

Unusual Parasitic Infections

Nematodes

Ghai RR, Chapman CA, Omeja PA, Davies TJ, Goldberg TL. 2014. Nodule worm infection in humans and wild primates in Uganda: cryptic species in a newly identified region of human transmission. *PLoS Negl Trop Dis* **8:**e2641. doi:10.1371/journal.pntd.0002641.

Soil-transmitted helminths continue to be a major health concern in many areas throughout the world. *Oesophagostomum* infection among humans and other primates is endemic in West Africa and has also been found in Uganda (3,000 km from identified foci in West Africa) and East Africa. These nodule worms are found in the gastrointestinal tracts of many mammals; some tend to be found in particular hosts, while others are much less host specific. Eight species of *Oesophagostomum* have been recorded in wild primates, three of which are the most common and can infect humans: *Oesophagostomum bifurcum*, *Oesophagostomum stephanostomum*, and *Oesophagostomum aculeatum*. The authors used routine and molecular methods to identify these infections. Based on these studies, it appears that ***Oesophagostomum* infection in humans may be common throughout sub-Saharan Africa, and there is great genetic diversity within this genus. There is also cross-species transmission among humans and other primates within this area.**

Eberhard ML, Ruiz-Tiben E. 2014. Cutaneous emergence of *Eustrongylides* in two persons from South Sudan. *Am J Trop Med Hyg* **90:**315–317.

Two large, viable worms were collected from the lower limbs of two individuals in South Sudan. The worms were seen as a part of the South Sudan Guinea Worm Eradication Program surveillance actions in areas thought to be at risk for Guinea worm disease (*Dracunculus medinensis*). **The worms (7 and 8 cm) were identified as fourth-stage larvae of *Eustrongylides*. This is the only case report of these worms emerging from the skin; the five earlier publications on human infection required surgery for worm removal from the peritoneal cavity.**

Cestodes

Roesel C, Welter S, Stamatis G, Theegarten D, Tappe D. 2014. Management of a chest-wall soft-tissue tumor caused by an infection with the larval tapeworm pathogen *Taenia crassiceps*. *Am J Trop Med Hyg* **91:**541–543.

A chest-wall lesion in an immunocompetent patient led to a presumptive diagnosis of a malignancy. Histopathology and PCR identified the larval stage of *Taenia crassiceps*. The tumor was surgically removed. Treatment options for immunocompromised and immunocompetent patients were reviewed. *Taenia crassiceps* causes a rare human tapeworm infection and is primarily found in the Holarctic region as an infection that circulates between canids and rodents. An increased number of cases have been reported in recent years. Of the infected patients, 47% were immunocompromised because of AIDS or hematological malignancy. Hematoma or traumatically altered or inflamed tissue appears to be a predilection site for an infection. Transmission occurs by infective eggs. No commercial serological tests are available; however, cross-reactions occur between *Taenia solium* and *T. crassiceps*. The larvae proliferate by posterior budding, making complete resections very difficult. In immunocompromised patients or patients with parasites located in the eye or brain, additional therapy with albendazole and praziquantel is recommended, as is monitoring for disease recurrence.

Trematodes

Gállego L, González-Moreno O, Gracenea M. 2014. Terrestrial edible landsnails as vectors for geographic dissemination of *Brachylaima* species. *J Parasitol* **100:**674–678.

Cornu aspersum (= syn. *Helix aspersa*) snails imported into northeast Spain from Algeria and South Africa are purchased in markets for human consumption. Samples of these snails were analyzed related to the possible geographic dissemination of *Brachylaima* species. Prevalence and viability studies of metacercariae were performed on Algerian and South African *Brachylaima* worms. Variables (16) in metacercariae and adults (18) were investigated. **Imported edible *C. aspersum* snails contribute significantly to the potential geographic spread of *Brachylaima* trematodes by harboring infective metacercariae which could easily infect animals.** Geographic spread could be enhanced by commerce in terrestrial snails such as *C. aspersum*.

Jung WT, Lee KJ, Kim HJ, Kim TH, Na BK, Sohn WM. 2014. A case of *Echinostoma cinetorchis* (Trematoda: Echinostomatidae) infection diagnosed by colonoscopy. *Korean J Parasitol* **52:**287–290.

Echinostomiasis is a foodborne intestinal trematode infection, primarily in Southeast Asia and the Far East. Human cases in Korea and Japan have been occasionally diagnosed through worm extraction via endoscopy. Most of these infections were caused by *Echinostoma hortense*. The authors detected two live worms of *Echinostoma cinetorchis* in the ascending colon of a Korean man (68 years old) admitted with intermittent right lower quadrant abdominal pain for 5 days. During colonoscopy, one worm was found attached to the proximal ascending colon, and the other was seen on the mid-ascending colon. Both worms were removed from the mucosal surface and identified as *E. cinetorchis* from the characteristic head crown (37 collar spines including 5 end-group ones on both sides), the lack of testes, and eggs measuring 108×60 μm with abopercular wrinkles. After therapy with praziquantel, the patient's symptoms disappeared. **Although the patient had a history of eating raw beef and raw fish, the infection source in this case is probably raw frogs eaten 2 months ago. This is the first case of endoscopy-diagnosed *E. cinetorchis* infection in Korea.**

Antibody and Antigen Detection in Parasitic Infections (General Immunology) (See Also Individual Relevant Chapters)

Protozoa

Marin C, Concha-Valdez F, Canas R, Gutierrez-Sanchez R, Sanchez-Moreno M. 2014. Anti-*Trypanosoma cruzi* antibody detection in eastern Andalusia (Spain). *Trans R Soc Trop Med Hyg* **108:**165–172.

Although we tend to think of *Trypanosoma cruzi* infections as being from Latin America, they are also endemic in other areas. Currently, Spain has the highest prevalence in Europe. The authors tested eight diagnostic tests for antibody in 550 blood specimens; a range of values from 1.1 to 4.2% were obtained. The highest percentage was obtained using the ELISA detection of semi-purified superoxide dismutase excreted by *T. cruzi* (ELISA-SODe). **Based on these results, antibody detection using this particular biomarker could be used for either screening and/or confirmatory testing.**

Helminths

Mounsey K, Kearns T, Rampton M, Llewellyn S, King M, Holt D, Currie BJ, Andrews R, Nutman T, McCarthy J. 2014. Use of dried blood spots to define antibody response to the *Strongyloides stercoralis* recombinant antigen NIE. *Acta Trop* **138:**78–82.

Serologic testing for the diagnosis of *Strongyloides stercoralis* infection using the NIE antigen has proven to be very effective; the NIE antigen is a 31-kDa recombinant antigen obtained from the L3-stage larvae. **The authors report on antibody detection from dried blood spots,** primarily for improved sample collection and specimen storage requirements. Results using this approach agreed with earlier study results and confirmed the high seroprevalence of strongyloidiasis in Australian indigenous communities.

General Immunology

Protozoa

Tan JJ, Capozzoli M, Sato M, Watthanaworawit W, Ling CL, Mauduit M, Malleret B, Grüner AC, Tan R, Nosten FH, Snounou G, Rénia L, Ng LF. 2014. An integrated lab-on-chip for rapid identification and simultaneous differentiation of tropical pathogens. *PLoS Negl Trop* Dis **8:**e3043. doi:10.1371/journal.pntd.0003043.

In this study, a microfluidic lab-on-chip integrating multiplex molecular amplification and DNA microarray hybridization was developed for simultaneous detection and species differentiation of 26 globally important tropical pathogens. Test performance for each pathogen ranged from 10^2 to 10^3 DNA or RNA copies. This lab-on-chip approach was evaluated using 170 retrospective patient specimens from Singapore and Thailand with sensitivity and specificity as follows: 83.1% and 100% for *Plasmodium falciparum*; 91.3% and 99.3% for *Plasmodium vivax*; 90.0% and 100% for Chikungunya virus; and 85.0% and 100% for Dengue virus serotype 3 compared to reference methods. **These test results confirm the feasibility of an amplification microarray-based approach for detection and identification of certain tropical pathogens.**

Rodrigues V, Cordeiro-da-Silva A, Laforge M, Quaissi A, Akharid K, Silvestre R, Estaquier J. 2014. Impairment of T cell function in parasitic infections. *PLoS Negl Trop Dis* **8:**e2567.

It is well known that T cell responses are extremely important in the development of protective immunity against parasitic infections. **However, eradication of these infections is rarely accomplished, thus resulting in the subsequent development of chronic infections.** This chronic state often leads to a loss of T cell function (T cell exhaustion). There are key differences between T cell exhaustion (antigen persistence, chronic activation, loss of cytotoxic or helper activities) and T cell anergy (impaired antigen presentation, reduced costimulation). Specific organisms discussed include *Leishmania* spp., *Plasmodium* spp., *Toxoplasma gondii*, and *Trypanosoma cruzi*. These intracellular organisms also tend to inhibit T cell memory and reduce the overall number of T cells available over time.

Treatment (See Also Individual Relevant Chapters)

Thriemer K, Van Hong N, Rosanas-Urgell A, Phuc BQ, Ha DM, Pockele E, Guetens P, Van Van N, Duong TT, Amambua NA, D'Alessandro U, Erhart A. 2014. Delayed parasite clearance after treatment with dihydroartemisinin-piperaquine in *Plasmodium falciparum* malaria patients in central Vietnam. *Antimicrob Agents Chemother* **58:**7049–7055.

Decreased susceptibility of *Plasmodium falciparum* toward artemisinin-based drugs has been well documented from the Thai-Cambodian border and from the Thai-Myanmar border. The authors conducted a 42-day *in vivo* and *in vitro* efficacy study, in which treatment was monitored and blood samples were collected twice daily until the smears were negative. Also, genotyping, qPCR, and sensitivity testing were completed. Parasite clearance time was 61.7 hours; the PCR was estimated to be 100% at day 28 and 97.7% at day 42. At day 3, the *P. falciparum* prevalence by genotyping quantitative PCR was 2.5 times higher than by microscopy. **In central Vietnam, the effectiveness of dihydroartemisinin-piperaquine (DHA-PPQ) remains acceptable, but overall clearance times and rates confirm emerging artemisinin resistance.**

García-Bournissen F, Moroni S, Marson ME, Moscatelli G, Mastrantonio G, Bisio M, Cornou L, Ballering G, Altcheh J. 2015. Limited infant exposure to benznidazole through breast milk during maternal treatment for Chagas disease. *Arch Dis Child* **100:**90–94

Benznidazole (BNZ) is a safe and effective drug for the treatment of Chagas' disease in children. However, in adults it is contraindicated during breastfeeding, since BNZ transfer into breast milk has not been thoroughly investigated. BNZ was measured in plasma and milk from women and their breastfed infants on admission and on the 7th and 30th days of therapy, and then monthly for 6 months. **Limited transfer of BNZ into breast milk and normal clinical findings in the babies suggest that BNZ treatment for Chagas' disease during breast feeding is relatively risk-free for the baby.**

Liu YX, Wu W, Liang YJ, Jie ZL, Wang H, Wang W, Huang YX. 2014. New uses for old drugs: the tale of artemisinin derivatives in the elimination of *Schistosomiasis japonica* in China. *Molecules* **19:**15058–15074.

Artemisinin (qinghaosu) and its three major derivatives—artemether, artesunate, and dihydroartemisinin—have proven to be effective against all species of the malaria parasite. Since the early 1980s, these drugs have also been confirmed as being effective against *Schistosoma* spp. and have been used to prevent and treat schistosomiasis in China. **Currently, in China, praziquantel is the only available drug used for the treatment of *Schistosomiasis japonicum* infections. In the national control program, this drug has been used for more than 30 years. Although no evidence of praziquantel resistance has been detected in isolates of *S. japonicum*, resistance has been produced in the laboratory. This fact strongly suggests that *S. japonicum* may eventually develop resistance.** Although China's goal is schistosomiasis elimination, potential development of praziquantel resistance may prevent reaching this goal. Unfortunately, reduced sensitivity to artemether, artesunate, and dihydroartemisinin has also been seen in praziquantel-resistant *S. japonicum.*

Saunders DL, Vanachayangkul P, Lon C, U.S. Army Military Malaria Research Program, National Center for Parasitology, Entomology, and Malaria Control (CNM), Royal Cambodian Armed Forces. 2014. Dihydroartemisinin-piperaquine failure in Cambodia. *N Engl J Med* **37:**484–485.

Dihydroartemisinin-piperaquine, one of the only drugs effective against multidrug-resistant *Plasmodium falciparum,* was adopted as the primary antimalarial drug in Cambodia in 2010. The authors conducted a trial evaluating the effectiveness of dihydroartemisinin-piperaquine for uncomplicated *P. falciparum* malaria. Adults with parasite loads of 1,000 to 200,000 parasites per cubic millimeter were given 3 days of dihydroartemisinin-piperaquine treatment (cumulative doses, 360 mg of dihydroartemisinin and 2,880 mg of piperaquine), with 42 days of follow-up. Dihydroartemisinin-piperaquine has been effective in Africa and Southeast Asia; however, the high failure rate in this study compared with 2010 is the second report of poor clinical outcomes in Cambodia. **Increased treatment failures, parasite clearance times, and piperaquine IC_{50} values (doubled) from 2010 to 2013 indicate continued developing resistance to both drug components.**

Nagel R, Bielefeldt-Ohmann H, Traub R. 2014. Clinical pilot study: efficacy of triple antibiotic therapy in *Blastocystis* positive irritable bowel syndrome patients. *Gut Pathog* **6:**34.

***Blastocystis* spp. are the most commonly reported gut protozoa worldwide, an infection that has been linked to irritable bowel syndrome (73% versus 27% in controls).** Although many changes in the enteric and nervous system in these patients, particularly those with diarrhea-predominant **irritable bowel syndrome**, have been documented, specific changes have been linked to *Blastocystis* spp. infections. These changes include the following: activation of IL-8, increased permeability in colonic epithelial cells, and degradation of IgA (possibly from cysteine proteases). Although metronidazole has been the drug of choice, results vary from 0 to 100%, and often retreatment is required. **In the study patients (14 days of diloxanide furoate, trimethoprim-sulfamethoxazole, and secnidazole), 60% were organism-free at 6 weeks, suggesting that triple antibiotic therapy may be a good alternative to single antibiotic therapy.**

Testing of Stool Specimens

Parija SC, Mandal J, Ponnambath DK. 2014. Laboratory methods of identification of *Entamoeba histolytica* and its differentiation from look-alike *Entamoeba* spp. *Trop Parasitol* **4:**90–95.

Entamoeba histolytica causes intestinal and extraintestinal amebiasis and is a common parasitic cause of morbidity and mortality in many countries. Detection and differentiation of pathogenic *E. histolytica* from nonpathogenic *Entamoeba* spp. (*Entamoeba dispar*, *Entamoeba moshkovskii*, *Entamoeba bangladeshi*) are important in patient management. Most diagnostic tests currently in use fail to differentiate among the *Entamoeba* spp. Molecular-based methods are more sensitive, easy to perform, more widely used, and can differentiate the various species. DNA microarray technology has been found to be another promising tool for the diagnostic and epidemiological evaluation of amebiasis.

Stark D, Roberts T, Ellis JT, Marriott D, Harkness J. 2014. Evaluation of the EasyScreen™ enteric parasite detection kit for the detection of *Blastocystis* spp., *Cryptosporidium* spp., *Dientamoeba fragilis*, *Entamoeba* complex, and *Giardia intestinalis* from clinical stool samples. *Diagn Microbiol Infect Dis* **78:**149–152.

The authors evaluated the EasyScreen Enteric Parasite Detection Kit (Genetic Signatures, Sydney, Australia) for the detection and identification of five enteric human parasites on 358 fecal specimens: *Blastocystis* spp., *Cryptosporidium* spp., *Dientamoeba fragilis*, *Entamoeba* complex, and *Giardia intestinalis*. Compared with PCR and microscopy, the EasyScreen Enteric Parasite Detection Kit resulted in 92 to 100% sensitivity and 100% specificity. No cross-reactivity with other bacterial, viral, and/or protozoan species was seen. The EasyScreen Kit does not detect *Cystoisospora belli* or *Cyclospora cayetanensis*, and it does not differentiate between pathogenic and nonpathogenic *Entamoeba* spp.

APPENDIX 8

Molecular Panels for Parasitology

Reagents contain ingredients that could be irritating or caustic if they come in contact with skin, eyes, or mucous membranes. Wear gloves, safety glasses, and laboratory coat, and use standard laboratory precautions when handling. If swallowed, call a physician. In case of skin or eye contact, flush with copious amounts of water. *Pathogenic microorganisms including hepatitis viruses and human immunodeficiency virus may be present in clinical specimens*. Proper handling and disposal methods should be established. Wipe up spillage of patient specimens immediately and disinfect with an appropriate disinfectant. Treat the cleaning materials as biohazardous waste.

The test options listed below are examples of Food and Drug Administration (FDA)-approved molecular diagnostic tests for parasites. In the future, we expect to see more test options, since many test parasite panels are currently under development.

A. APTIMA *Trichomonas vaginalis* Assay

Although there are many molecular methods for identifying parasites published in the literature, most of these tests were developed in-house and have not been approved by the FDA. However, there are several FDA-approved molecular diagnostic tests for parasites, including the APTIMA *Trichomonas vaginalis* Assay (GenProbe, San Diego, CA). The APTIMA *Trichomonas vaginalis* Assay is a nucleic acid test that utilizes target capture, transcription-mediated amplification (TMA), and hybridization protection assay (HPA) technologies that have previously been used for detection of *Neisseria gonorrheae* and *Chlamydia trachomatis*. It also accepts the same specimen types (i.e., clinician-collected vaginal and endocervical swabs, female urine, and PreservCyt solution). However, urine, vaginal swab, and PreservCyt Solution liquid Pap specimen sampling are not designed to replace cervical exams and endocervical specimens for diagnosis of female urogenital infections. Patients may have cervicitis, urethritis, urinary tract infections, or vaginal infections due to other causes or concurrent infections with other agents. Reliable results depend on adequate specimen collection. Because the transport system used for this assay does not permit microscopic assessment of specimen adequacy, training of clinicians in proper specimen collection techniques is necessary.

The APTIMA assay provides high sensitivity and specificity and does not require organism viability or motility. There are approximately 7 million new cases of *T. vaginalis* infection in the United States per year (1). This figure probably represents an underestimate of the disease burden, considering that there are no recommended screening guidelines and the most commonly used testing methods such as wet mounts and culture are insensitive. Clinical infection is associated with cervical neoplasia, cervical carcinoma, tubal infertility, posthysterectomy infection, pelvic inflammatory disease, preterm rupture of membranes, preterm birth, low birth weight infants, neonatal infection, and increased transmission of HIV (2). It has been estimated that 10 to 50% of *T. vaginalis* infections in women are asymptomatic, and in men the proportion may even be higher (3–7). It is important to remember that therapeutic failure or success cannot be determined with the APTIMA *Trichomonas vaginalis* Assay since nucleic acid may persist following appropriate antimicrobial therapy.

KEY POINTS

1. A negative result does not exclude a possible infection since results depend on adequate specimen collection. Test results may be affected by improper specimen collection, technical error, specimen mix-up, or target levels below the assay limit of detection.
2. A negative result does not exclude a possible infection because the presence of *Trichomonas tenax* or *Pentatrichomonas hominis* in a specimen may affect the ability to detect *T. vaginalis* rRNA. However, these organisms are relatively rare and may not present a problem. Also, performance of the APTIMA *Trichomonas vaginalis* Assay has not been evaluated in the presence of *Dientamoeba fragilis*.
3. The APTIMA *Trichomonas vaginalis* Assay provides qualitative results. Therefore, a correlation cannot be drawn between the magnitude of a positive assay signal and the number of organisms in a specimen.
4. If a specimen contains few *T. vaginalis* organisms, uneven distribution of the trichomonads may occur, which may affect the ability to detect *T. vaginalis* rRNA in the collected material. If negative results from the specimen do not fit with the clinical impression, a new specimen may be necessary.
5. This test has not been FDA cleared for male clinical specimens.

B. Affirm VPIII Microbial Identification Test

The Affirm VPIII DNA probe technology (Becton Dickinson and Co, Franklin Lakes, NJ) provides a dependable, rapid means for the differential detection and identification of three organisms causing vaginitis: *Candida* species, *Gardnerella vaginalis*, and *T. vaginalis* (8, 9). The test features an easy-to-read color reaction that is more accurate than current microscopic methods such as wet mounts and culture for the detection of the causative agents of vaginitis. Also, the test performance is not affected by "difficult specimens" (collected during menstruation, after intercourse), self-medication, or the presence of mixed infections.

The test uses two distinct single-stranded nucleic acid probes for each organism, a capture probe and a color development probe, that are complementary to unique genetic sequences of the target organisms. The capture probes are immobilized on a bead embedded in a probe analysis card (PAC), which contains a separate bead for each target organism. The color development probes are contained in a multiwell reagent cassette. During the procedure, the assay aligns complementary nucleic acid strands to form specific, double-stranded complexes called hybrids. For each of the three organisms, this hybrid is composed of capture and color development single-stranded nucleic acid probes, complementary to the released target nucleic acid analyte. Enzyme conjugate then binds to the captured analyte, thus providing the test results. A positive result is a visible blue color reaction on the organism-specific bead embedded in the Affirm PAC. Each PAC contains three test beads, one for each organism, plus positive and negative control beads to ensure test quality. The total time to results is under 45 min, with less than 2 min of hands-on time needed. The simple, automated procedure can be performed with minimal training.

KEY POINTS

1. When using the Affirm VPIII Ambient Temperature Transport System (ATTS): The total time *between sample collection and proceeding with sample preparation should be no longer than* 72 h when the specimen is stored at ambient conditions (15 to 30°C). The system has also been qualified for transport use at refrigerated conditions (2 to 8°C).
2. The Affirm VPIII Microbial Identification Test includes two internal controls on each PAC: a positive control bead and a negative control bead. These control beads are tested simultaneously with each patient specimen, ensuring the proper performance of the PAC, reagent cassette, and processor. The positive control also ensures the absence of specimen interference. The negative control also ensures the absence of nonspecific binding from the specimen.
3. The assay is intended to be used with the Affirm VPIII Ambient Temperature Transport System, the Affirm VPIII Sample Collection Set, or the swabs provided in the Affirm VPIII Microbial Identification Kit. Other methods of collection have not been evaluated. Optimal test results require appropriate specimen collection. Test results may be affected by improper specimen collection, handling, and/or storage conditions. A negative test result does not exclude the possibility of vaginitis/vaginosis.
4. Vaginitis/vaginosis is most frequently caused by *G. vaginalis*, *Candida* species, and *T. vaginalis*. Vaginitis symptoms may also be seen in toxic shock syndrome (caused by *Staphylococcus aureus*) or may be caused by nonspecific factors or by specific organisms. Mixed infections may occur. Therefore, a test indicating the presence of *Candida* species, *G. vaginalis*, and/or *T. vaginalis* does not rule out the presence of other organisms. Bacterial vaginosis is not caused by a single organism, but is thought to reflect a shift in the vaginal flora.
5. The performance of this test on patient specimens collected during or immediately after antimicrobial therapy is unknown. The presence or absence of *Candida* species, *G. vaginalis*, or *T. vaginalis* cannot be used as a test for therapeutic success or failure.

C. BD MAX Enteric Parasite Panel

The BD MAX Enteric Parasite Panel (Becton, Dickinson and Company, Sparks, MD) is a multiplex qualitative *in vitro* diagnostic test that simultaneously and differentially detects DNA from *Giardia lamblia*, *Cryptosporidium* (*Cryptosporidium hominis* and *Cryptosporidium parvum*), and *Entamoeba histolytica* in unpreserved and preserved (10% formalin) stool specimens (10–12). These pathogens represent commonly isolated and highly pathogenic organisms. Results from this assay are available in approximately 4 hours, require minimal technologist time, and may replace traditional methods such as microscopy and immunoassay.

Positive results do not rule out coinfection with other organisms that are not detected by this test and may not be the sole cause of patient illness. Negative results in the setting of clinical illness compatible with gastroenteritis and/or colitis may be due to infection by pathogens that are not detected by this test or noninfectious causes such as ulcerative colitis, irritable bowel syndrome, or Crohn's disease.

A soft to diarrheal stool is collected, homogenized, and looped into a sample buffer tube (SBT). The SBT is closed with a septum cap and heated on the BD prewarm heater to lyse the parasite organisms. The SBT is then vortexed and transferred to the BD MAX system. The cells are lysed, nucleic acids are extracted on magnetic beads and concentrated, and then an aliquot of the eluted nucleic acids is added to PCR reagents which contain the target-specific primers used to amplify the genetic targets. The assay also includes a sample processing control (SPC), which is present in the extraction tube and undergoes the extraction, concentration, and amplification steps to monitor for inhibitory substances or instrument or reagent failure. The BD MAX system automates sample lysis, nucleic acid extraction and concentration, reagent rehydration, nucleic acid amplification, and detection of the target nucleic acid sequence using real-time PCR. Amplified targets are detected with hydrolysis probes labeled with quenched fluorophores. The amplification, detection, and interpretation of the signals are done automatically by the BD MAX system.

KEY POINTS

1. To avoid amplicon contamination, do not break apart the BD MAX PCR cartridges after use. The seals of the BD MAX PCR cartridges are designed to prevent contamination.
2. In cases where open-tube PCR tests are conducted in the laboratory, care must be taken to ensure that the BD MAX Enteric Parasite Panel, any additional reagents required for testing, and the BD MAX system are not contaminated. Gloves must be changed before manipulating reagents and cartridges.
3. BD MAX Enteric Parasite Panel components are stable at 2 to 25°C through the stated expiration date. Do not use expired components.
4. A BD MAX Enteric Parasite Panel positive result does not necessarily indicate the presence of viable organisms. It indicates the presence of DNA from *E. histolytica*, *G. lamblia*, *C. parvum*, or *C. hominis*, allowing for identification of the BD MAX Enteric Parasite Panel organisms.
5. As with all PCR-based *in vitro* diagnostic tests, extremely low levels of target below the analytical sensitivity of the assay may be detected, but results may not be reproducible. False negatives may also occur if the level of organism nucleic acid is below the threshold of detection.
6. False negative results may occur due to loss of nucleic acid from inadequate collection, transport, or storage or due to inadequate organism lysis. The SPC has been added to the test to aid in the identification of specimens that contain inhibitors to PCR amplification. The SPC does not indicate if nucleic acid has been lost due to inadequate collection, transport, or storage or whether cells have been inadequately lysed.
7. BD MAX Enteric Parasite Panel results may or may not be affected by concurrent antimicrobial therapy, which may reduce the amount of target present.
8. The performance of this test has not been established for monitoring treatment of *G. lamblia*, *C. hominis*, *C. parvum*, or *E. histolytica*. This test is a qualitative test and does not provide quantitative values or indicate the quantity of organisms present.
9. The performance of this test has not been evaluated for immunocompromised individuals or for patients without symptoms of gastrointestinal infection.
10. The effect of interfering substances has only been evaluated for those listed in this labeling. Potential interference has not been evaluated for substances other than those described in the "Interference" section.
11. Cross-reactivity with organisms other than those listed in the "Analytical Specificity" section of the package insert has not been evaluated.

D. BioFire FilmArray Gastrointestinal Panel

The FilmArray Gastrointestinal Panel (BioMérieux, Marcy l'Etoile, France) is designed for the simultaneous detection of 22 enteric pathogens directly from stool specimens: *Campylobacter* spp. (*Campylobacter jejuni*, *Campylobacter coli*, *Campylobacter upsaliensis*), *Clostridium difficile* (toxin A/B), *Plesiomonas shigelloides*, *Salmonella*, *Vibrio* spp. (*Vibrio Parahaemolyticus*, *Vibrio vulnificus*, *Vibrio cholerae*), *Yersinia enterocolitica*, enteroaggregative *Escherichia coli*, enteropathogenic *E. coli*, enterotoxigenic *E. coli*, Shiga-like toxin-producing *E. coli* (*stx1/2*), STEC O157, *Shigella*/enteroinvasive *E. coli*, *Cryptosporidium* spp., *Cyclospora cayetanensis*, *E. histolytica*, *G. lamblia* (*Giardia intestinalis*, *Giardia duodenalis*) Adenovirus F 40/41, Astrovirus, Norovirus GI/GII, Rotavirus A, and Sapovirus (Genogroups I, II, IV, and V) (13–15). This test is a qualitative test and does not provide a quantitative value for the organism(s) in the sample.

The FilmArray GI pouch is a closed, disposable system that houses all the chemistry required to isolate, amplify, and detect nucleic acid from multiple gastrointestinal pathogens within a single stool specimen. The rigid plastic component (fitment) of the FilmArray GI pouch contains reagents in freeze-dried form. The flexible plastic portion of the pouch is divided into discrete segments (blisters) where the required chemical processes are carried out. The user of the FilmArray GI Panel loads the sample into the FilmArray GI pouch, places the pouch into the FilmArray instrument, and starts the run. All other operations are automated.

The sample volume requirement is 200 µl. The FilmArray GI Panel test consists of automated nucleic acid extraction, reverse transcription, amplification, and analysis, with results available in 1 hour per run (i.e., per specimen). Each FilmArray pouch contains an internal nucleic acid extraction control and a PCR control. FilmArray GI Panel runs are considered valid if the run completes normally and internal controls are passed. The FilmArray software performs automated result analysis with each target in a valid run reported as "Detected" or "Not Detected." If either internal control fails, the software automatically provides a result of "Invalid" for all panel analytes.

KEY POINTS

1. Stool samples may contain a high concentration of organisms. To avoid possible contamination, samples should be processed in a biosafety cabinet. If a biosafety cabinet is not used, a dead air box, a splash shield, or a face shield should be used when preparing samples. A biosafety cabinet or work station that is used for performing stool pathogen testing (e.g., culture, enzyme immunoassay) should not be used for sample preparation or pouch loading.

(continued)

KEY POINTS *(continued)*

2. Prior to processing a sample, thoroughly clean both the work area and the FilmArray pouch loading station using a suitable cleaner such as freshly prepared 10% bleach or a similar disinfectant. To avoid residue build-up and potential PCR inhibition, wipe disinfected surfaces with water. Samples and pouches should be handled one at a time. Change gloves and clean the work area between each sample.
3. Stool specimens should be collected in Cary Blair transport media according to the manufacturer's instructions. A 200-µl sample is required for testing. Specimens should be processed and tested as soon as possible, though they may be stored at room temperature or under refrigeration for up to 4 days.
4. The RNA Process Control assay targets an RNA transcript from the yeast *Schizosaccharomyces pombe*. The freeze-dried yeast is present in the pouch and becomes rehydrated when the sample is loaded. The control material is carried through lysis, nucleic acid purification, reverse transcription, first-stage PCR, dilution, second-stage PCR, and DNA melting. A positive control result indicates that all steps carried out in the FilmArray GI pouch were successful.
5. The PCR2 control assay detects a DNA target that is dried into wells of the array along with the corresponding primers. A positive result indicates that second-stage PCR was successful.
6. Good laboratory practice recommends running external positive and negative controls regularly. Enteric transport media can be used as an external negative control. Previously characterized positive stool samples or negative samples spiked with well-characterized organisms can be used as external positive controls. External controls should be used in accordance with the appropriate accrediting organization requirements, as applicable.
7. Once melt curves have been identified, the software evaluates the three replicates for each assay to determine the assay result. For an assay to be called positive, at least two of the three associated melt curves must be called positive, and the melting temperature for at least two of the three positive melt curves must be similar (within 1°C). Assays that do not meet these criteria are called negative.
8. If four or more distinct organisms are detected in a specimen, retesting is recommended to confirm the polymicrobial result.
9. The FilmArray GI Panel contains two assays (Crypt 1 and Crypt 2) for detection of *Cryptosporidium* spp. Detection of approximately 23 *Cryptosporidium* spp. occurs, including the most common species of human clinical relevance (i.e., *C. hominis* and *C. parvum*), as well as several less common species (e.g., *Cryptosporidium meleagridis*, *Cryptosporidium felis*, *Cryptosporidium canis*, *Cryptosporidium cuniculus*, *Cryptosporidium muris*, and *Cryptosporidium suis*). The assays do not differentiate between *Cryptosporidium* spp. and the very rare species *Cryptosporidium bovis*, *Cryptosporidium ryanae*, and *Cryptosporidium xiaoi*, which may not be detected. A positive result for either or both assays will give a "*Cryptosporidium* Detected" test result.
10. The FilmArray GI Panel contains a single assay (Ehist) for the detection of *E. histolytica*, the only *Entamoeba* species implicated in gastroenteritis. This assay may cross-react with the closely related *Entamoeba dispar* when present at higher levels (approximately 10^5 organisms/ml or greater).
11. The "Result Summary" section of the test report lists the result for each target tested by the panel. Possible results for each organism are "Detected," "Not Detected," "Not Applicable (N/A)," or "Invalid." See the "Results Summary" section in the instruction booklet for detailed information about interpretation of test results and appropriate follow-up for "Invalid" results.
12. The performance of this test has only been validated with human stool collected in Cary Blair transport medium following the media manufacturer's instructions. It has not been validated for use with other stool transport media, raw stool, rectal swabs, endoscopy stool aspirates, or vomitus. Test performance has not been established for patients without signs and symptoms of gastrointestinal illness.
13. Virus, bacteria, and parasite nucleic acid may persist *in vivo* independent of organism viability. Additionally, some organisms may be carried asymptomatically. Detection of organism targets does not imply that the corresponding organisms are infectious or are the causative agents for clinical symptoms. The performance of this test has not been established for monitoring treatment of infection with any of the panel organisms.

E. Luminex

In January 2013, the FDA approved the first test that can simultaneously detect 11 common viral, bacterial, and parasitic (*Cryptosporidium*, *Giardia*) causes of infectious gastroenteritis from a single patient fecal specimen (xTAG Gastrointestinal Pathogen Panel [GPP], Luminex, Inc., Austin, TX) (14, 16–20). The xTAG GPP is a multiplexed nucleic acid test for the simultaneous qualitative detection and identification of multiple viral, parasitic, and bacterial nucleic acids in human stool specimens from individuals with signs and symptoms of infectious colitis or gastroenteritis.

The target is amplified using PCR or reverse transcription PCR, then analyzed with Luminex xTAG technology to detect the presence or absence of each pathogen in the panel. The test detects 11 gastrointestinal pathogen targets: *Campylobacter* (*C. jejuni*, *C. coli*, and *C. lari* only), *Clostridium difficile* toxin A/B, *Cryptosporidium* (*C. parvum* and *C. hominis* only), *E. coli* O157, enterotoxigenic *E. coli* (ETEC) LT/ST, *Giardia* (*G. lamblia* only, also known as *G. intestinalis* and *G. duodenalis*), Norovirus GI/GII, Rotavirus A, *Salmonella*, Shiga toxin-producing *E. coli* (STEC) stx1/stx2, and *Shigella* (*Shigella boydii*, *Shigella sonnei*, *Shigella flexneri*, and *Shigella dysenteriae*). The xTAG GPP is capable of delivering multiple results within 5 hours. The assay is cleared on the widely available Luminex 100/200 system. Additionally, simultaneous molecular testing on a single sample within a single shift provides significant benefit to laboratories in terms of workflow and resource utilization.

Human stool samples are pretreated and then subjected to nucleic acid extraction. For each sample, 10 µl of extracted nucleic acid is amplified in a single multiplex RT-PCR/PCR reaction. Each target or internal control in the sample results in PCR amplimers ranging from 58 to 202 bp (not including the 24-mer tag). A 5-µl aliquot of the RT-PCR product is then added to a hybridization/detection reaction containing bead populations coupled to sequences from the Universal Array ("antitags"), streptavidin, R-phycoerythrin conjugate. Each Luminex bead population detects a specific microbial target or control through a specific tag/anti-tag hybridization reaction. Following the incubation of the RT-PCR products with the xTAG GPP Bead Mix and xTAG Reporter Buffer, the Luminex instrument sorts and reads the hybridization/detection reactions. A signal or median fluorescence intensity is generated for each bead population. These fluorescence values are analyzed to establish the presence or absence of bacterial, viral, or parasitic targets and/or controls in each sample. A single multiplex reaction identifies all targets.

KEY POINTS

1. Due to the open system design of the platform, there is a potential for contamination. The "Intended Use" (package insert) of this device states that all positive results using the xTAG GPP assay are presumptive and need to be confirmed by another FDA-cleared or approved assay or acceptable reference method. All results should be used and interpreted in the context of a full clinical evaluation as an aid in the diagnosis of gastrointestinal infection. Confirmed positive results do not rule out coinfection with other organisms that are not detected by this test and may not be the sole or definitive cause of patient illness. Negative xTAG GPP results in the setting of clinical illness compatible with gastroenteritis may be due to infection by pathogens that are not detected by this test or noninfectious causes such as ulcerative colitis, irritable bowel syndrome, or Crohn's disease.
2. Analyte targets (virus, bacteria, or parasite nucleic acid sequences) may persist *in vivo*, independent of virus, bacteria, or parasite viability. Detection of analyte target(s) does not guarantee that the corresponding live organism(s) is present or that the corresponding organism(s) is the causative agent for clinical symptoms.
3. *Cryptosporidium*: the xTAG GPP assay detects *C. parvum* and *C. hominis* only.
4. *Giardia*: the xTAG GPP assay detects *G. lamblia* only (also known as *G. intestinalis* and *G. duodenalis*).
5. There is a risk of false-negative values due to the presence of strain/species sequence variability in the targets of the assay, procedural errors, amplification inhibitors in specimens, or inadequate numbers of organisms for amplification.
6. The performance of this test has not been established for monitoring treatment of infection with any of the panel organisms.
7. Positive and negative predictive values are highly dependent on prevalence. False-negative test results are more likely prevalent when disease is high. False-positive test results are more likely during periods when prevalence is low.
8. This test is a qualitative test and does not provide the quantitative value of detected organism present.
9. Known strains or positive clinical samples for the targeted viruses, bacteria, or parasites should be included in routine quality control procedures ("external controls") as positive controls for the assay. One or more of these external controls are analyte positive controls and should be included with each batch of patient specimens. Controls positive for different targets should be rotated from batch to batch. External controls should be prepared, extracted, and tested in the same manner as patient samples (http://www.accessdata.fda.gov/cdrh_docs/reviews/K121454.pdf).
10. Failure to correctly interpret test results in the context of other clinical and laboratory findings may lead to inappropriate or delayed treatment. For example, a microorganism present as a colonizer may be correctly detected but not be the true cause of illness. Although this identical risk would be present from the use of any microbiological assay in this setting, simultaneous testing of multiple analytes in a multiplex assay may be more likely to detect an unanticipated colonizer that might not be tested for individually.
11. It should be recognized that the device is intended for use as an aid in the diagnosis of gastroenteritis in conjunction with clinical presentation and the results of other laboratory tests. Both clinical presentation and other results would likely substantially mitigate concerns with both false-positive and false-negative test results.

F. Other Pending Molecular Tests

Several other molecular tests are in clinical trials for the detection of select gastrointestinal parasites. These tests are molecular gastrointestinal panels and target the most commonly occurring parasitic stool pathogens. Although there are laboratory-developed tests for most parasites, these are not commercially available or are available only in specialized testing centers. When such tests are used, attention should be given to the use of internal amplification controls to detect inhibition, since common specimens, such as blood and stool, contain PCR inhibitors. Thorough validation is required before these are implemented for clinical testing. Specific organisms under consideration include *E. histolytica*, *Blastocystis hominis* (*Blastocystis* spp.), and *D. fragilis*. Blood parasites include *Plasmodium* spp. (including *Plasmodium knowlesi*), *Trypanosoma* spp., and *Leishmania* spp.

APPENDIX 9

Frequently Asked Questions about Diagnostic Parasitology

As laboratory personnel become more widely cross-trained, the availability of people who have expertise in diagnostic parasitology will become more limited. Over the years, many questions have been asked regarding various aspects of diagnostic medical parasitology. Answers to these questions may be helpful for those working in this area of microbiology and may provide some "tips of the trade" that are learned through many years of bench experience.

FECAL SPECIMENS

SPECIMEN COLLECTION (1–4; this volume)

1. What has been the "gold standard" for stool collection systems?

The standard two-vial collection set has been used for many years and consists of one vial of 10% formalin from which the concentration is performed and one vial of liquid fixative (base fixative can be mercury [Schaudinn's fixative] or nonmercury to which has been added the plastic resin powder polyvinyl alcohol, PVA [stool adhesive]) from which the permanent stained smear is prepared.

2. What is the basis for the recommendation that three stools should be collected on alternate days, rather than 3 days in a row or three in one day?

Intestinal protozoa are shed in the stool on a cyclic basis. It is generally accepted that this time frame is approximately 10 days, so if specimens are collected too close together, sampling may occur at a low point in the cycle and the organisms may be missed. By collecting specimens over a wider time frame, days with heavier shedding may be sampled as well.

3. Can the laboratory accept three stools collected 3 days in a row?

Yes, but chances of sampling during the total time frame for shedding (10 days) might be more likely to include days of heavy shedding.

4. Is it ever appropriate to accept three stools in one day from the same patient?

Generally, the answer is no, with rare exceptions. If a patient has severe diarrhea or dysentery, there is a large dilution factor that may make finding any organisms present more difficult. Therefore, after consultation with the physician, more than one stool could be examined within any one day.

5. Is it good laboratory practice to accept two (rather than three) stools for the ova and parasite (O&P) examination?

Although the examination of three stool specimens provides a more statistically accurate result, many laboratories feel the percentage of organism recovery with the examination of two stools is acceptable. Percent recovery varies from ~80% to over 95% with the submission and examination of two stool specimens from a single patient. The examination of a single stool specimen is only about 50% accurate in the detection of parasites, especially intestinal protozoa. One study (5) found the following increases when examining the third stool:

- Yield increased 22.7%: *Entamoeba histolytica*
- Yield increased 11.3%: *Giardia lamblia*
- Yield increased 31.1%: *Dientamoeba fragilis*

6. Do you have to collect the stool specimen any differently if you are looking for the coccidia (*Cryptosporidium* spp., *Cyclospora cayetanensis*, or *Cystoisospora* [*Isospora*] *belli*)?

Fresh stool or specimens preserved in routine stool fixatives (formalin- or nonformalin-based) can be used for diagnostic procedures for the identification of the coccidial oocysts (special modified acid-fast stains for the coccidia or fecal immunoassays for *Cryptosporidium* spp.). Some of the single-vial collection options (Universal Fixatives, e.g., TOTAL-FIX) are also acceptable.

7. Do you have to collect the stool specimen any differently if you are looking for microsporidia?

Fresh stool or specimens preserved in routine stool fixatives (formalin- or nonformalin-based) can be used for diagnostic procedures (modified trichrome stains) for the identification of the microsporidial spores. Some of the single-vial collection options (Universal Fixatives) are also acceptable.

FIXATIVES AND ADHESIVES

1. What are the pros and cons of using stool fixatives?

Although it might be helpful to see motile organisms in the direct saline wet preparation, often the trophozoite forms have already begun to disintegrate by the time the stool specimen reaches the laboratory. **Trophozoites DO NOT ENCYST after the stool has left the body.** To reduce the lag time between passage of the specimen and submission/arrival in the laboratory, stool fixatives are recommended. However, if only preserved stool is submitted, immunoassays that require fresh or frozen stool (e.g., *E. histolytica* Ag, *E. histolytica/Entamoeba dispar* Ag, or Triage cartridge) cannot be performed. **The benefits of fixation and preservation of organism morphology far outweigh the benefits of receiving a fresh, unpreserved stool.**

2. When selecting a single-vial stool fixative, what questions should be asked?

Can one perform a concentration, permanent stained smear, special stains for the coccidia and microsporidia, fecal immunoassay procedures, and/or PCR from the specimen received in that vial (Universal Fixative)? What stains work best with that particular fixative? Another issue for consideration involves the types and numbers of parasites that might be missed using this approach.

3. What are the advantages and disadvantages of using 5% versus 10% formalin?

Although 5% formalin is thought to provide a more "gentle" fixation of protozoa, this concentration of formalin will not always kill all helminth eggs. The 10% formalin will kill most helminth eggs (exception: *Ascaris lumbricoides, Toxocara, Baylisascaris*) but may be more damaging to protozoa. Most people probably can't tell the difference by examining clinical specimens preserved in either 5% or 10% formalin, with the exception of helminth egg viability (containing motile larva—*Ascaris, Toxocara*).

4. What is the difference between buffered and nonbuffered formalin?

Buffered formalin tends to produce fewer osmotic changes in the organisms during fixation; however, on a day-to-day basis, it may be difficult to detect morphologic differences from buffered or unbuffered formalin.

5. Should the laboratory be concerned about the amount of formalin used in the parasitology lab? (Also see a complete discussion in the "Concentrations" section.)

The amount of formalin used in diagnostic parasitology testing is minimal. The regulations governing formalin use were developed for industry, where large amounts of formalin are sometimes used. However, the regulations do indicate that any facility using formalin must be monitored. Once you have been monitored and results do not exceed the stated limits and your records are on file, there is no need to be rechecked (unless something dramatically changes in terms of your formalin volume use). **We have never heard of any microbiology laboratory coming even close to the limits, so formalin use in diagnostic parasitology is perfectly acceptable.**

6. What is PVA (stool adhesive)?

PVA stands for polyvinyl alcohol, a plastic powder/resin that is incorporated into the liquid fixative (Schaudinn's or other fixatives) and serves as an adhesive to "glue" the stool material onto the slide. **PVA itself has no preservation capability and is inert in terms of fixation.**

7. What is albumin (stool adhesive)?

Egg albumin has been used as a stool adhesive, particularly when using sodium acetate-acetic acid-formalin (SAF) that does not contain PVA plastic resin (also an adhesive). However, with the development of Universal Fixatives, smears can be prepared without using PVA or albumin.

8. What are some good stool fixative/stain combinations?

The "gold standard" has been 1 vial of 10% formalin, from which the concentration is performed. The second vial has been with mercuric-chloride liquid fixative to which has been added PVA, from which the permanent stained smear is prepared and then stained (trichrome or iron hematoxylin). Other options in terms of overall quality are:

a. TOTAL-FIX and trichrome stain
b. SAF and iron hematoxylin stain
c. UNIFIX or Z-PV and trichrome stain
d. ECOFIX and ECOSTAIN (Meridian Bioscience)
e. SAF and trichrome stain (not as good as SAF and iron hematoxylin)

9. What are Universal Fixatives?

Examples of "Universal Fixatives" are TOTAL-FIX (no mercury, no PVA, no formalin), SAF (no mercury, no PVA; *contains formalin*), and ECOFIX (no mercury, no formalin; *contains PVA*). **Currently, TOTAL-FIX is the only fixative that contains no formalin, no PVA, and no mercury. TOTAL-FIX can be used without the addition of the PVA adhesive to the fixative; adequate drying time for smears prior to staining is the most important step (minimum of 30 min to 1 h in 37°C incubator—requires more time for thicker fecal smears).**

SPECIMEN PROCESSING (1–4; this volume)

Ova and Parasite Examination

1. What procedures constitute the O&P examination?

The direct wet mount, concentration, and permanent stained smear constitute the routine O&P examination on fresh stool specimens. **If the specimens are submitted to the laboratory in stool preservatives, then the concentration and permanent stained smear should be performed; the direct wet mount is not required, since no motility will be visible.** If a laboratory indicates that it provides an O&P examination, the CAP checklist indicates that the O&P examination must include the concentration and permanent stained smear. Also, the CAP checklist requires that the direct wet smear be performed on **fresh** liquid or soft stool only (looking for motile trophozoites). There is no need to perform a direct wet mount on fresh formed stool; the possibility of seeing motile trophozoites is rare, since formed stool tends to contain only the cyst forms.

2. Why do you need to perform a permanent stained smear examination on every stool submitted for an O&P examination?

There are data to indicate that intestinal protozoa may or may not always be seen and identified from the concentration examination. **Since the permanent stained smear is designed to facilitate identification and/or confirmation of the intestinal protozoa, it is important that this procedure be performed on all stools for which the O&P has been ordered.** Also, since trophozoite stages will not be visible on the concentration examination (formalin-based fixatives; however, if present, trophozoites are often visible in concentration sediments prepared from the nonformalin-based fixatives [single-vial systems]), it is even more important to examine the permanent stained smear. Even if organisms (trophozoites and/or cysts) are seen in the concentration wet mount, they might not be identified accurately and will require confirmation from the examination of the permanent stained smear. Remember, patients who are symptomatic with diarrhea are more likely to have protozoan trophozoites in the stool, not the more resistant cyst form. This approach is consistent with the O&P examination (CAP checklist for laboratory inspections).

3. Why do you need to pour out some PVA onto paper towels prior to preparation of slides for permanent staining?

The reason this step has been included in processing directions is the following: some people were taking the PVA/stool right out of the vial and onto the slide; too much PVA was being carried over onto the slide. It takes quite a bit of time for PVA to dry, so the material often falls off during staining because the thick PVA is not yet dry. **Also, the amount of PVA (plastic powder) it takes to glue the stool onto the slide is extremely small.** So if you eliminate the excess PVA prior to making the smears, your slides will require less drying time, the stool will adhere to the glass, and you will get a better stained smear. However, if the material (PVA/stool mixture) is taken right out of the vial onto the glass slide and this approach is working (no excess PVA), there is no need to change protocols. Note: If TOTAL-FIX is being used, no PVA is used; however, drying time prior to staining is still very important.

4. Can you use concentrated sediment to prepare slides for permanent staining?

The main thing to remember is that **a routine permanent stain (e.g., trichrome stain) cannot be performed from the concentration sediment if the specimen was originally preserved in formalin or has been rinsed using formalin, saline, or water.** One can perform a trichrome stain on SAF-preserved material, but not if the specimen has been rinsed with formalin, saline, or water. If you centrifuge the fecal/fixative material (without adding any rinse reagents), then providing your fixative is compatible with the permanent stain you are using, you can use some of the sediment for smear preparation prior to staining. However, once you continue with the rinse steps, the final concentration sediment will often (again depending on the rinse fluids) not be compatible with trichrome staining. **If you want to use a single-vial fixative system (TOTAL-FIX), then you can spin down the stool/fixative mixture (using no additional rinse reagents), prepare your slide for permanent staining from the sediment, and then proceed with the regular rinses called for in the concentration procedure.**

DIAGNOSTIC METHODS (1–4; this volume)

Direct Wet Examinations

1. What is the purpose of the direct wet examination (saline versus iodine)?

This procedure is designed to allow the viewer to detect motile trophozoites (using saline); this procedure should not be performed on preserved specimens and should be reserved for fresh stool specimens that are very soft or liquid. Often, the organism identification will be presumptive; permanent stained smears will also need to be examined. If iodine is added to the direct wet mount, organism morphology may be more easily seen, but the organisms will be killed, and thus no motility will be visible.

2. How should the direct wet preparation be examined?

The entire coverslip preparation (22 × 22 mm) should be examined under low magnification (×100, 10× objective); approximately 1/3 to 1/2 of the coverslip preparation should be examined under high dry magnification (×400, 40× objective). **It is not practical to examine this preparation using oil immersion magnification (e.g., ×1,000, 100× or ×600, 60× oil immersion objectives).** Saline and/or iodine mounts can be examined; however, iodine will kill any organisms present, so trophozoite motility will no longer be visible.

3. What do you expect to see during a direct wet preparation examination?

Helminth eggs and/or larvae can be seen, as well as some protozoan cysts, trophozoites (primarily in fresh direct wet preparations from soft or liquid stool), white blood cells (WBCs), some yeast, and fecal debris. Many of the intestinal protozoa will need to be confirmed using the oil immersion magnification (×1,000, 100× oil immersion objective) for the permanent stained smear.

Concentrations

1. What is the recommended time and speed for centrifugation for the concentration method? Why is this important?

The current recommendation is for every centrifugation step in the concentration method (sedimentation) to be performed for **10 min at 500 × *g*.** If this recommendation is not followed, then small coccidian oocysts and microsporidial spores may not be recovered in the concentrate sediment. The number of organisms is greatly increased over taking the sample from the unspun specimen.

2. What is the purpose of the concentration procedure?

The purpose of the concentration is to concentrate the parasites present, either through sedimentation or flotation. The concentration is specifically designed to allow recovery of protozoan cysts, coccidian oocysts, microsporidian spores, and helminth eggs and larvae.

3. Why is the flotation concentration used less frequently than the sedimentation concentration?

There are several reasons. First, **not all parasites will float; therefore, you need to examine both the surface film and the sediment before indicating that the concentration examination is negative.** Second, the organisms must not be left in contact with the high specific gravity zinc sulfate for too long or protozoa will tend to become distorted, so the timing of the examination is more critical. Also, the specific gravity of the fluid will need to be checked periodically.

4. What specific gravity of zinc sulfate should be used for the flotation concentration procedure?

If the concentration is being performed on fresh stool, the specific gravity of the solution should be 1.18. However, if the concentration is being performed on stool preserved in a formalin-based fixative, the specific gravity of the zinc sulfate should be 1.20.

5. How should the concentration wet preparation be examined?

Formalin-ethyl acetate (substitute for ether) sedimentation concentration is the most commonly used concentration procedure. Zinc sulfate flotation will not detect operculated or heavy eggs (e.g., unfertilized *Ascaris* eggs, operculated cestode, and/or trematode eggs); both the surface film and sediment need to be examined before reporting a negative result if the flotation method is used. Smears prepared from concentrated stool are normally examined as for the direct wet mount using the low power objective (10×) and the high dry power objective (40×); use of the oil immersion objective (100×) is not recommended (organism morphology is not that clear). The addition of too much iodine may obscure helminth eggs (will mimic debris).

6. What semiautomated methods are available to read the concentration sediments?

The traditional sampling approach using pipettes and the preparation of wet smears using glass slides and coverslips can be replaced with a semiautomated sampling and viewing system from FE-5 (Apacor Ltd., Brooklyn, NY). The specimen is drawn through tubing from the mixed concentrated stool sediment into two viewing chambers that fit onto the microscope stage. The quality of the glass is excellent, and organism morphology can be easily seen within the viewing chambers. Selection of such a system often depends on the laboratory work load.

7. Are there any tips for specimen processing for detection of the microsporidia?

When early comparisons of methods were performed, the authors used a slower centrifugation compared with using unspun material. Using these methods, they felt that using unspun material was better for recovery of microsporidial spores. **However, at UCLA when we looked carefully at this approach compared with the 500 × *g* for 10 min (standard centrifugation time and speed), we found considerably more spores in the sediment.** If the stool contains a lot of mucus or is runny, just add formalin and centrifuge. Don't bother with ethyl acetate since it may pull much of the material you want to examine up into the mucus layer. If the stool is not particularly watery or doesn't contain a lot of mucus, you can treat it just like a regular concentration (but remember to make every spin at 500 × *g* for 10 min). Also, the more you manipulate a stool, the more likely you will lose some organisms (this applies to all parasites in stool). So you may want to eliminate the wash steps and work with the first sediment you obtain from the first spin.

Remember to make the smears thin (this will help you see the spores), and also remember not to decolorize too much. Filtration is not a problem using any of the commercial concentration systems. If you are using gauze, make sure you use woven gauze and use only two layers (do not use pressed gauze, which is too dense and will trap parasites).

8. Comment on the use of formalin within the microbiology laboratory (6–9; this volume)

The formalin regulations were originally developed for industry (plywood, etc.), where large amounts of formalin are used in manufacturing processes. The amount of formalin we are exposed to in the laboratory is minimal; we've never heard of any microbiology laboratory (including a full-service parasitology service) even coming close to the limits.

> The Occupational Safety and Health Administration (OSHA) amended the original regulations for occupational exposure to formaldehyde in May of 1992 [1:Fed Regist 1992 May 27;57(102):22290-328]. The final amendments lower the permissible exposure level for formaldehyde from 1 ppm (part per million) as an 8-hour time-weighted average (TWA) to an 8-hour time-weighted average of 0.75 ppm. The amendments also add medical removal protection provisions to supplement the existing medical surveillance requirements for those employees suffering significant eye, nose or throat irritation and for those suffering from dermal irritation or sensitization from occupational exposure to formaldehyde. In addition, changes have been made to the standard's hazard communication and employee training requirements. These amendments establish specific hazard labeling for all forms of formaldehyde, including mixtures and solutions composed of 0.1% or greater of formaldehyde in excess of 0.1 ppm. Additional hazard labeling, including a warning that formaldehyde presents a potential cancer hazard, is required where formaldehyde levels, under reasonably foreseeable conditions of use, may potentially exceed 0.5 ppm. The final amendments also provide for annual training of all employees exposed to formaldehyde at levels of 0.1 ppm or higher. (6)

Those laboratories that have been monitored have not come close to either measurement. Once a laboratory has been measured and the results (below thresholds for regulatory requirements) are on file, this information does not need to be generated again. No badges are required. Even without a fume hood (many labs do not use a fume hood), performing the routine formalin–ethyl acetate concentration does not seem to be a problem. A number of people who have indicated they want to remove formalin from the laboratory probably don't really understand the history of the regulation or the actual issues. The only possible problem seen in the clinical laboratory/pathology setting might be a routine anatomical pathology laboratory where very large amounts of formalin are used—and with sloppy use. However, even within large microbiology laboratories, it does not seem to be a problem. Appendix B to CFR 1910.1048 (9) contains "Sampling Strategy and Analytical Methods for Formaldehyde." Ultimately, the removal of formalin from the laboratory is based on an individual laboratory decision (keeping in mind the exposure limits indicated below).

> **TWA:** The employer shall ensure that no employee is exposed to an airborne concentration of formaldehyde which exceeds 0.75 parts formaldehyde per million parts of air (0.75 ppm) as an 8-hour TWA (time weighted average).
>
> **STEL:** The employer shall ensure that no employee is exposed to an airborne concentration of formaldehyde which exceeds two parts formaldehyde per million parts of air (2 ppm) as a 15-minute STEL (short-term exposure limit).

Permanent stains

1. What is the purpose of the permanent stained smear?

The purpose of the permanent stained smear (trichrome, iron-hematoxylin) is to provide contrasting colors for both the background debris and parasites present; it is designed to allow examination and recognition of detailed organism morphology under oil immersion examination (100× oil immersion objective for a total magnification of ×1,000). This examination is primarily designed to allow recovery and identification of the intestinal protozoa.

2. How long should one examine the permanent stained smear?

Rather than responding with a specific number of minutes, the recommendation is to examine at least 300 oil immersion (×1,000 total magnification) fields; additional fields may be required if suspect organisms have been seen in the wet preparations from the concentrated specimen.

3. What recent changes have influenced the overall quality of the permanent stained smear?

The use of mercury substitutes in fecal fixatives generally leads to diminished overall morphology quality of the intestinal protozoa. However, some of the mercury substitutes (zinc-based) provide morphologic quality that is close to mercury and allows identification of most of the intestinal protozoa. Differences in detection and identification are usually comparable unless there are very few organisms present or the organisms are quite small. In these circumstances, some organisms may be missed using mercury substitutes. **The development of TOTAL-FIX (no mercury, no formalin, no PVA) provides a fixative that results in excellent overall protozoan morphology.** Although this product is patented (Medical Chemical Corporation, Torrance, CA), there are other fixation options under development with similar characteristics.

4. What is the purpose of the iodine dish in Wheatley's trichrome stain protocol?

Mercury is removed from the smear when placed in the iodine dish; there is a chemical substitution of iodine for mercury. The iodine is removed during the next two alcohol rinses. Therefore, when the slide is placed in trichrome stain, no mercury or iodine remains on the fecal smear.

5. Why don't you need to use the iodine dish when staining fecal smears prepared from specimens preserved in the newer single-vial systems (zinc sulfate-based fixative)?

The zinc sulfate-based fixative is water soluble, so the dry smears can be placed directly into the trichrome dish without having to go through the iodine and subsequent rinse steps. The zinc sulfate will be removed by the water in the trichrome stain.

6. Why might you have to use the iodine dish and subsequent rinses in your staining setup when staining slides from the proficiency testing agencies (AAB, various states, etc.)?

Some smears used for proficiency testing are prepared from fecal specimens that have been preserved in mercury-based fixatives, so the iodine dish and subsequent rinse steps are required to remove mercury and iodine prior to staining with either trichrome or iron hematoxylin stains. For several years, some of the proficiency testing agencies have been using specimens that have been preserved in nonmercury fixatives; thus, the iodine dish is not required.

7. What role does the acetic acid play in the trichrome stain?

Both the trichrome and iron hematoxylin stains are considered regressive stains; the fecal smears are overstained and then destained. The 1% acetic acid in the 90% alcohol rinse step in the trichrome stain removes some of the stain and provides better contrast. However, in some cases differences in the quality of staining between stained protozoa that have been subjected to the 90% alcohol rinse with and without the acetic acid may be difficult to detect. It is important not to destain the smears too much; overall organism morphology will be diminished.

8. What causes the xylene (or xylene substitute) dehydration solutions to turn cloudy when a slide from the previous alcohol dish is moved forward into the xylene dish?

If there is too much water carryover from the last alcohol dish, the xylene solution may turn cloudy. When this occurs, replace the 100% alcohol dishes, back up the slide into 70% alcohol (you can also use a series of steps: 95% then 70%), allow it to stand for 15 min, and then move the slide forward through the 100% alcohol steps and xylene steps.

9. Why is absolute ethanol (100%) recommended as the best approach?

Although many laboratories use the commercially available 95/5% denatured alcohol mix as their "absolute alcohol," the dehydration of stained fecal smears will not be as good as that obtained with 100% ethanol. You may want to add an additional dish of the denatured alcohol (absolute alcohol) to your staining set-up to obtain better dehydration.

10. What is the difference between xylene and xylene substitutes?

There are several differences. As a safety measure, most laboratories have decided to eliminate xylene from their laboratories. However, xylene substitutes generally do not dehydrate as well. Also, after the slides are removed from the last dish of xylene substitute, they take longer to dry. You may want to add an additional dish of the xylene substitute to your staining set-up to obtain better overall dehydration.

11. How do stained fecal smears differ when the fixative does and does not contain PVA?

Although PVA is inert, the material does stain; there will be some background "haze" associated with PVA on the permanent stain. When staining TOTAL-FIX (no PVA present), the background will be quite clean, and the organisms tend to stain a bit more pale. It is important to remember not to destain too long (two quick dips in the 90% alcohol containing 1% acetic acid is sufficient), then immediately move into the first absolute alcohol. Use this dish as a wash, and then begin dehydration in the second absolute alcohol dish; then move smears into the xylene substitute.

STOOL IMMUNOASSAY OPTIONS

1. What are some of the immunoassay options available for stool protozoa? How do they rank in terms of sensitivity and specificity?

Currently, immunoassays are available for *G. lamblia*, *Cryptosporidium* spp., the *E. histolytica*/*E. dispar* group, and *E. histolytica*. Reagents for the detection of *D. fragilis*, *Blastocystis* spp., and the microsporidia are under development. All of the fecal immunoassay test formats are comparable in terms of sensitivity and specificity. Selection of a particular method depends on work flow and the number of test requests and personal preference of that particular laboratory. Outside of the United States (non-FDA approved), there are also reagents available for some of the microsporidia.

2. What methods are available commercially?

Direct fluorescence (DFA), enzyme immunoassay (EIA), and cartridge formats (membrane flow or a solid phase qualitative immunochromatographic procedure) are currently available.

3. Why might someone want to use a fecal immunoassay option?

If the most common organisms found in the area are *Giardia*, *Cryptosporidium*, and/or the *E. histolytica*/*E. dispar* group, then fecal immunoassays are certainly options. Specific patients/history/symptoms would suggest the use of fecal immunoassays. **Both the O&P examinations and fecal immunoassays are recommended for a laboratory test menu; both would be orderable, billable procedures, depending on the patient history and symptoms.**

4. How would stool immunoassay requests fit into a laboratory that also performs O&P examinations?

Any diagnostic laboratory performing routine parasitology testing should offer both options: routine O&P examinations and the fecal immunoassays. **Both the O&P examinations and fecal immunoassays are recommended for a laboratory test menu; both would be orderable, billable procedures.**

5. What do you mean by the "routine O&P examination"?

This test includes (fresh material: liquid or semiliquid stools) a direct wet exam, the concentration, and the permanent stain; preserved specimens would require a concentration and permanent stained smear (no direct wet mount is required).

6. How would you fit the fecal immunoassays into your laboratory?

Per separate requests, you could offer the routine O&P examination, and you could also offer on request the stool immunoassay option. Both options should be in the laboratory ordering test menu.

7. What type of educational initiatives would have to be undertaken prior to offering these options?

Physicians would need to know the pros and cons of ordering either the immunoassay or the routine O&P examination. **Refer to Table A9.1 on test ordering.**

8. What are some of the pros and cons for the fecal immunoassays?

Pros:

- Depending on the format selected, the immunoassays are fast and relatively simple to perform.
- The result can "rule in or out" very specific organisms.
- If the patient becomes asymptomatic at the time the immunoassay is negative, additional testing may not be necessary.
- May help reduce personnel costs (time to perform procedures).
- The fecal immunoassays are more sensitive than the routine O&P exams and/or the special stains for the coccidia or microsporidia.

Cons:

- The fecal immunoassay kits test **only** for selected organisms.
- Depending on the format, they might be somewhat complex to perform.
- Test requests may not justify certain formats (cost, equipment, or training).
- It is critical that the physician realize that a negative immunoassay will not rule out all possible parasitic etiologic agents causing diarrhea.
- ***Giardia lamblia* may require a fecal immunoassay on two different stool specimens to get a positive result. This is not the case for other protozoa** (10, 11).

9. Can the fecal immunoassays be used for duodenal fluid (giardiasis)?

First, the tests have NOT been approved or validated for this type of specimen. Also, the duodenal fluid/aspirate would contain primarily the trophozoite form, not the cyst stage for which the reagents have been designed. An example: if one is using the FA (rather than EIA or cartridge), the trophs may appear to be fluorescent at a very pale 1+, while the cysts are a strong 3 to 4+. So while there may be a few antigenic sites that are shared by the cysts and trophs, the commercial tests for *Giardia* are designed primarily to detect the cyst antigens.

You can try the reagents on these specimens, but if the result is negative, the result in no way has ruled giardiasis out. I would recommend testing stool only; if the result is positive, this ap-

TABLE A9.1 Stool testing order recommendations (for physicians)

Patient and/or situation	Test ordered[a]	Follow-up test ordered
Patient with diarrhea and AIDS or other cause of immune deficiency Potential waterborne outbreak (municipal/city water supply)	*Cryptosporidium* or *Giardia*/*Cryptosporidium* immunoassay	If immunoassays are negative and symptoms continue, special tests for microsporidia (modified trichrome stain) and other coccidia (modified acid-fast stain) and O&P exam should be performed
Patient with diarrhea (nursery school, day care center, camper, backpacker) Patient with diarrhea and potential waterborne outbreak (resort setting) Patient with diarrhea from areas where *Giardia* is the most common parasite found	*Giardia* or *Giardia*/*Cryptosporidium* immunoassay (perform testing on two stools before reporting as negative) **Particularly relevant for areas of the United States where *Giardia* is the most common organism found**	If immunoassays are negative and symptoms continue, special tests for microsporidia and other coccidia (see above) and O&P exam should be performed
Patient with diarrhea and relevant travel history Patient with diarrhea who is a past or present resident of a developing country Patient in an area of the United States where parasites **other than** *Giardia* are found	O&P exam, *Entamoeba histolytica*/*E. dispar* immunoassay; immunoassay for confirmation of *E. histolytica*; various tests for *Strongyloides* may be relevant (even in the absence of eosinophilia)	If exams are negative and symptoms continue, special tests for coccidia and microsporidia should be performed
Patient with unexplained eosinophilia and possible diarrhea; if chronic, patient may also have history of respiratory problems (larval migration) and/or sepsis or meningitis (hyperinfection)	Although the O&P exam is a possibility, the agar plate culture for *Strongyloides stercoralis* (more sensitive than the O&P exam) is recommended	If tests are negative and symptoms continue, additional O&P exams and special tests for microsporidia and other coccidia should be performed
Patient with diarrhea (suspected foodborne outbreak)	Test for *Cyclospora cayetanensis* (modified acid-fast stain, autofluorescence)	If tests are negative and symptoms continue, special procedures for microsporidia and other coccidia and O&P exam should be performed

[a] Depending on the particular immunoassay kit used, various single or multiple organisms may be included. Selection of a particular kit depends on many variables: clinical relevance, cost, ease of performance, training, personnel availability, number of test orders, training of physician clients, sensitivity, specificity, equipment, time to result, etc. Very few laboratories will handle this type of testing exactly the same. Many options are clinically relevant and acceptable for good patient care. It is critical that the laboratory report indicate specifically which organisms could be identified using the kit; a negative report should list the organisms relevant to that particular kit.

proach might avoid the need for duodenal aspirate testing altogether.

10. Comment on the use of the *Giardia* fecal immunoassay; how many specimens should be tested before assuming the patient is negative?

Since the evidence indicates that *Giardia* is shed sporadically, and that more than one immunoassay might be required to diagnose the infection, the recommendation is similar to that for stool collection for the routine O&P examination: **for *Giardia*, perform the immunoassay on two different stools (assuming the first specimen is negative),** collected within no more than a 10-day period; a good collection schedule would be day one, then day three or four. That way, one would assume one of those collections would yield a positive result if the organisms (in sufficient numbers) are present. However, you also have to remember that **if the patient is a carrier with a low organism load, even the second immunoassay might be negative. Note: One stool is sufficient for immunoassay testing for *Cryptosporidium* spp.**

11. Although an FA for *Cryptosporidium/Giardia* was negative, the O&P concentrate showed *Giardia* trophs on the wet mount. Might we miss positive *Giardia* if only the FA is ordered? Also, do any of the EIA antigen tests detect both trophs and cysts, and should we switch to one of those?

Although the antibody in the immunoassay kits is to the cyst antigen (primarily, but it is a polyclonal reagent), in some of the kits the trophs do fluoresce, but much less intensely (around a 1+, maybe even a 2+, thus indicating some shared epitopes). In almost all patients, there will be a combination of cysts and trophs, unless the patient has active diarrhea and is passing only trophs (no time for cysts to form with rapid passage through the

GI tract). However, most patients will have cysts as well, and the results (if above the test limits for sensitivity) will be positive. The situation you describe can happen, but it's probably not that common. **However, with ONLY trophs present, you may get a negative result. Some of the kits tend to provide a bit higher fluorescence with the troph, but it varies.**

12. After the patient has been treated, how long will the *Giardia* antigen test remain positive?

It has been recommended that you test about 7 days after therapy, hopefully to avoid picking up residual antigen. However, if you wait too long (several weeks), you run the risk of picking up antigen from a possible reinfection. Some people believe that low antigen levels can be found for up to about 2 weeks. A good time frame for retesting would probably be about 7 to 10 days after therapy. If the first specimen at 7 days is still positive, then you could retest at 10 to 12 days. **Also, we know that the immunoassays (for diagnosis) may not pick up low antigen loads (organism shedding issues), and thus the recommendation for diagnostic immunoassay testing for giardiasis has been changed, and performing immunoassay testing on one additional stool specimen (if the first one is negative) is recommended. The testing on two different stool specimens should be performed within about 3 to 5 days.**

13. Why do fecal immunoassay kits that test for either *Entamoeba histolytica* or the *Entamoeba histolytica/E. dispar* group require fresh or frozen stools or stools submitted in Cary-Blair?

Unfortunately, at the present time, these reagents will not function properly on preserved fecal specimens. Although the manufacturers are trying to develop such kits, they are not yet available.

14. How long will antigen survive in fresh stools?

It is recommended that fresh stools be tested within 24 h of collection; they can be stored overnight in the refrigerator. They can also be frozen or preserved in 10% formalin prior to testing (both freezing and/or formalin preservation methods will preserve antigen for long periods of time—even years).

ORGANISM IDENTIFICATION (1–4; this volume)

Protozoa

1. What is the most effective technique for the identification of the intestinal protozoa?

Although some protozoan cysts can be seen and identified on the wet preparation smear (direct mount, concentration sediment wet mount), the permanent stained smear is the procedure that is recommended as the most relevant and accurate for the identification of the intestinal protozoa. These preparations are examined using the oil immersion objective (100×) for a total magnification of ×1,000. At least 300 oil immersion fields should be examined prior to reporting the permanent stained smear result.

2. Are trophozoites ever seen in the wet mounts of stool?

Usually the trophozoites are not seen in the concentration sediment wet mount preparations unless they are prepared from stool preserved in a fixative containing no formalin. Motile trophozoites can occasionally be seen in the direct wet smear prepared from fresh soft or liquid stool that is more likely to contain trophozoites, but this is rare.

3. What are some tips to consider when reporting *Entamoeba hartmanni*?

The measurements of 10 µm or less for the *E. hartmanni* cyst refer to wet preparation measurements, so the measurement should be decreased ~1 µm on the permanent stained smear. When you see a cyst on the permanent stained smear, there is often a halo representing shrinkage. **The cyst needs to be measured to include that halo.** On the bench, the measurements for this cyst generally run from around 9.5 down to about 8 µm, and they are morphologically definitely *E. hartmanni*. The *E. hartmanni* cyst generally contains more chromatoidal bars than are seen in *E. histolytica/E. dispar* and often stops at two nuclei, rather than four. Also, the *E. histolytica/E. dispar* cysts tend to measure routinely on the bench (trichrome slides) from about 10.5 up to about 13 µm or so. Also, on the bench, the *E. hartmanni* nucleus in the trophozoite will tend to look like a bull's-eye—very sharp line of nuclear chromatin with the karyosome right in the middle.

4. Do nonpathogenic protozoa ever cause symptoms?

Endolimax nana, *Iodamoeba bütschlii*, *Chilomastix mesnili*, and *Pentatrichomonas hominis* (for example) have been categorized as nonpathogens. Although rare, patients have been documented who have been symptomatic with a nonpathogen. However, it is sometimes difficult to determine from the case history the extent of the workup, including coccidia and the microsporidia. Before assigning symptoms to nonpathogenic protozoa, a comprehensive search for other proven pathogens should be performed.

5. What are some of the considerations when reporting *Entamoeba histolytica* versus the *Entamoeba histolytica/E. dispar* group?

Morphologically, unless the trophozoite measures >12 µm and contains ingested RBCs, the identification must be *Entamoeba histolytica/E. dispar*, indicating that the true pathogen (*E. histolytica*) cannot be differentiated from the nonpathogen (*E. dispar*). One can also report the true pathogen if the fecal immunoassay specific for *E. histolytica* is positive. Since *Entamoeba moshkovskii* and *Entamoeba bangladeshi* also look very much like others in the *Entamoeba* genus, some people have suggested that they should be reported as the "*Entamoeba histolytica* complex."

6. What color is the autofluorescence seen with *Cyclospora cayetanensis*?

The color depends on the particular FA filters used. If Calcofluor white filters are used, the oocysts will appear as pale blue rings; if FITC filters are used, the oocysts will appear to be more yellow-green. Fluorescence intensity will vary from about 1+ to 2+; it is rare to see stronger autofluorescence with these oocysts.

7. Why is *Blastocystis hominis* so controversial regarding pathogenicity?

What we currently call *Blastocystis hominis* (morphologically) appears to be approximately 10 to 20 different strains, subtypes, or species, some of which are pathogenic and some of which are nonpathogenic. Based on continuing molecular studies, changes in the classification of this group are probable. If all strains, subtypes, and species currently make up what is called "*Blastocystis hominis*," this could explain the controversy regarding pathogenicity and the fact that some patients are symptomatic, while some are asymptomatic. Unfortunately, all of the strains, subtypes, and species are morphologically identical; therefore, the correct identification reported continues to be *Blastocystis* spp. (*B. hominis*), and the number should be quantitated from the permanent stained smear (rare, few, moderate, many, packed). Many laboratories have begun reporting *Blastocystis* spp., with a report comment explaining the pathogenic versus nonpathogenic controversy. This is the recommended approach.

Helminths

1. Why can't all helminth eggs be recovered using the flotation concentration rather than the sedimentation concentration?

Some helminth eggs are quite heavy (e.g., unfertilized *Ascaris* eggs) and will not float, even using zinc sulfate with a specific gravity of 1.20. Other helminth eggs are operculated; when the egg is placed in a high specific gravity solution, the operculum "pops" open and the egg fills with fluid and sinks to the bottom of the tube. Thus, both the surface film and the sediment should be examined before reporting the specimen as negative.

2. Why do helminth larvae need to be identified to the species level; shouldn't all larvae recovered in stool be that of *Strongyloides stercoralis*?

Although helminth larvae in stool are normally *Strongyloides stercoralis*, there is always the possibility that in fresh stool hookworm eggs have continued to mature and may hatch before the stool is processed and/or placed in fixatives. It is important to make sure that the larvae seen are, in fact, the rhabditiform (noninfectious) larvae of *S. stercoralis* rather than larvae of hookworm. The agar plate culture is the most sensitive method for the recovery of *S. stercoralis* larvae. Also, remember that migrating nematode larvae could also be recovered from respiratory specimens (sputum, BAL, etc.).

3. Are there any specific recommendations for the detection of schistosome eggs?

When trying to diagnose schistosomiasis, regardless of the species suspected, you should examine both stool (several different stool specimens) and urine (spot urines plus 24-hour specimen) (collected with no preservatives). Occasionally, adult worms get into blood vessels, where they aren't normally found (example: *Schistosoma mansoni* eggs found in urine only). When you perform a sedimentation concentration, use saline to prevent premature egg hatching. Once you are ready to try a hatching procedure, then you can put the sediment into spring water (dechlorinated water) to stimulate hatching. When examining wet mounts under the microscope, you need to look for the movement of cilia on the miracidium larvae within the egg shell (thus the need to collect the specimens with no preservatives). You want to be able to tell the physician whether the eggs, if present, are viable or all you see are dead egg shells. If you suspect schistosomiasis, it is recommended that you examine a number of wet mounts, particularly if you aren't going to perform a hatching test.

4. What is the most sensitive test for the diagnosis of strongyloidiasis?

Agar plate cultures are recommended for the recovery of *Strongyloides stercoralis* larvae and tend to be more sensitive than some of the other diagnostic methods such as the O&P examination. Stool is placed onto agar plates, and the plates are sealed to prevent accidental infections and held for 2 days at room temperature. As the larvae crawl over the agar, they carry bacteria with them, thus creating visible tracks over the agar. The plates are examined under the microscope for confirmation of larvae, the surface of the agar is washed with 10% formalin, and final confirmation of larval identification is made via wet examination of the sediment from the formalin washings.

In a study looking at the prevalence of *S. stercoralis* in three areas of Brazil, the diagnostic efficacy of the agar plate culture method was as high as 93.9% compared to only 28.5% and 26.5% by the Harada-Mori filter paper culture and fecal concentration methods, respectively, when fecal specimens were processed using all three methods. Among the 49 positive samples, about 60% were confirmed as positive using only the agar plate method. These results indicate that the agar plate approach is probably a much more sensitive diagnostic method and is recommended for the diagnosis of strongyloidiasis.

It is important to remember that more than half of *S. stercoralis*–infected individuals have low-level infections. The agar plate method continues to be documented as a more sensitive method than the usual direct smear or fecal concentration methods. Daily search for furrows on agar plates for up to 6 consecutive days results in increased sensitivity for diagnosis of both *S. stercoralis* and hookworm infections. **Also, a careful search for *S. stercoralis* should be made in all patients with comparable clinical findings before deciding on a diagnosis of idiopathic eosinophilic colitis, because consequent steroid treatment may have a fatal outcome by inducing widespread dissemination of the parasite.** Serologic testing for antibody is also recommended if strongyloidiasis is still suspected in the absence of laboratory confirmation of larvae.

5. Where can one get serologies for a *Baylisascaris procyonis* infection?

CDC:
1-404-718-4745 (M-F 7:30 am – 4 pm EST)
After-hours emergencies: 1-770-488-7100

REPORTING

Organism

1. Should common or scientific names be used when reporting the presence of parasites?

The scientific name (genus, species) should be used on the final report that goes to the physician and to the patient's chart. It is also recommended that the stage of the organism be included (trophozoite, cyst, oocyst, spore, egg, larvae, adult worm); various stages of the malaria parasites will impact therapy (see section on blood parasites in this appendix, below).

2. What happens if there are several different names used in the literature (*Giardia lamblia, G. intestinalis, G. duodenalis*)?

It is appropriate to use the most commonly accepted name (*G. lamblia*); you can also let the proficiency testing organism lists be your guide. When a replacement name begins to appear on the proficiency test list, then it's appropriate to notify your clients and institute the name change. Remember, it is very important to notify all clients prior to making any name changes.

3. How has the reporting of *Cryptosporidium parvum* changed, and why?

More than one species of *Cryptosporidium* can cause disease in humans (*C. parvum*: humans and other mammals; *C. hominis*: humans; and other less common species). However, the different species cannot be differentiated on the basis of morphology. **It is now recommended that the more correct reporting format would be *Cryptosporidium* spp. (rather than *C. parvum*).**

4. Should WBCs and/or other cells or yeast be reported, and why?

The reporting and quantitation (rare, few, moderate, many) of WBCs (polymorphonuclear leukocytes [PMNs], macrophages, eosinophils) provide some additional information for the physician. If the patient continues to have diarrhea, it may give the physician something more to consider, particularly if stool culture has not been ordered. Also, conditions related to noninfectious diarrheas may also result in WBCs and macrophages in the stool. We always include this type of information/explanation in our educational process regarding reporting formats. Physicians can then decide on the relevance of the information. Remember that when reporting WBCs we can also identify eosinophils from the permanent stained smear (may or may not be related to parasitic infection and may or may not correlate with peripheral eosinophilia; this information may also be helpful).

Reporting yeast is a bit different. To report anything about yeast, you must know the stool was fresh or immediately put in preservative. If there are lots of yeasts, budding yeasts, and/or pseudohyphae, then this provides some additional information for the physician, often depending on the patient's general condition and whether or not the patient is immunosuppressed. However, if you don't know whether the collection criteria were met, then reporting anything about yeast is NOT recommended, since this type of report may be misleading. Certainly, in these circumstances, the physician can be notified directly.

5. How should *Blastocystis hominis* be reported?

In the past there was some agreement that the number of organisms present (mod, many, packed) was more likely to be associated with symptoms. However, in the past few years, there have been anecdotal reports of patients being symptomatic with rare or few organisms. The current recommendation is to report the organism and quantitate per rare, few, mod, many, packed (using your proficiency testing quantitation scheme). It is important to confirm that the physicians know what the report means and understand the pathogenicity issues surrounding this organism; they can then correlate the numbers with symptoms. If rare or few, there are no solid data per number relevance other than the anecdotal case reports (many of which are word of mouth). Many physicians treat if the patient is symptomatic and no other organisms are found (including coccidia and/or microsporidia).

"*Blastocystis hominis*" includes several strains, subtypes, and species, some of which are pathogenic and some of which are nonpathogenic. Based on continuing molecular studies, changes in the classification of this group could be updated. If pathogenic and nonpathogenic strains, subtypes, or species make up what is morphologically called "*Blastocystis hominis*," this could explain the controversy regarding pathogenicity and the fact that some patients are symptomatic, while some are asymptomatic. Unfortunately, strain, subtype, and species differences cannot be detected by morphology; they look alike. **You should begin reporting *Blastocystis* spp. rather than *B. hominis*. It is also recommended that a report comment be included regarding strains, subtypes, or species and pathogenicity.**

6. How should intestinal protozoa be reported?

Reporting trophozoites/cysts: This has been the accepted way of reporting intestinal protozoa for a couple of reasons. First, different drugs are used to treat *Entamoeba histolytica* cysts versus trophs. Also, since the cyst form is the infective stage for the protozoa (exception: the trichomonads), the report does convey some epidemiologic information. For these reasons, the current recommendation is to continue to report all protozoa (genus, species, and stage).

7. What additional reporting comments should be added to the reporting of the O&P examination and the fecal immunoassays?

It is important to add the following comment to the O&P examination:

> "The O&P examination is not designed to detect the intestinal coccidia (*Cryptosporidium* spp., *Cyclospora cayetanensis*) or the microsporidia. *Cystoisospora belli* oocysts (coccidia) can be detected from the concentration sediment examination."

Report the results of the fecal immunoassays based on the specific organism(s) relevant to the kit:

> "No *Giardia lamblia* antigen detected." OR "*Giardia lamblia* antigen present."
>
> "No *Giardia lamblia* or *Cryptosporidium* spp. antigen detected."

OR

> "Negative for *Giardia lamblia*."
>
> "Negative for *Giardia lamblia* and *Cryptosporidium* spp."

The report of* Blastocystis *spp. should be accompanied by the following report comment:

> "*Blastocystis* spp. (morphologically) comprise a number of different strains, subtypes, or species, some of which are pathogenic and some of which are nonpathogenic. This explains why some patients are symptomatic and some are asymptomatic."

Quantitation

1. What organisms should be quantitated in the final report to the physician and patient's chart?

Organisms and nonorganism cells/structures (stool blood cells, Charcot-Leyden crystals) that are recommended for quantitation include the following:

A. Intestinal protozoa: *Blastocystis* spp.
B. Helminths: *Trichuris trichiura* eggs, *Clonorchis sinensis* eggs, schistosome eggs (also report viability of *Schistosoma* spp. eggs)
C. Blood parasites: all malaria organisms and *Babesia* spp.
D. Blood cells (PMNs, macrophages, RBCs)
E. Charcot-Leyden (CL) crystals

2. Why are all proficiency testing (PT) specimen answers reported and quantitated, while clinical specimen reports are rarely quantitated in terms of organism numbers?

There are two issues to consider.

1. When reporting PT specimen results, you are asked to quantitate organisms in both the formalin wet mounts and permanent stained smears. This information serves as a **quality control check for the proficiency testing agency to ensure that organism numbers are consistent throughout the challenge vials/slides.**
2. Most laboratories (with few organism exceptions) do not quantitate organisms on the concentration or permanent stained smear reports. Some exceptions might be *Trichuris trichiura* eggs in a concentration wet mount (light infections might not be treated). Since many organisms are shed on a random basis, quantitation may change dramatically from day to day and generally has little clinical relevance.

PROFICIENCY TESTING (1–5, 12; this volume)

Wet Preparations

1. How should you examine a wet preparation for proficiency testing?

Most directions recommend that you shake the vial and take a sample from the mixed vial contents. However, if the number of eggs is few, you may be better off taking a very small drop from the settled material. If you take too large a drop, it will be too thick to examine properly. Make sure you do not add too much iodine; very darkly stained helminth eggs can resemble debris.

2. Are there any tips regarding the microscope setup for the examination of an unstained wet preparation?

The microscope should be aligned properly using Köhler illumination. Make sure the light is not too bright; otherwise, you may shine right through the organisms and miss the parasites. Also, you may want to close the diaphragm a bit to provide more contrast. Extra contrast is particularly important when reading with saline only (no iodine added).

PERMANENT STAINED SMEARS

1. How should you examine a permanent stained fecal smear for proficiency testing?

Make sure the light is very bright (condenser all the way up) and the diaphragm is open. Review both thin and thick areas of the smear; examine at least 300 oil immersion fields (using the 100× oil immersion objective) before you report the specimen as a negative. If you use the 50× or 60× scanning oil immersion lens, you still need to review 300 oil fields as indicated above (using the 100× oil immersion objective).

TISSUES OR FLUIDS (1–4, 12; this volume)

1. How should tissues be submitted to the laboratory?

Tissue specimens should be immediately sent to the laboratory and kept moist during transit. If the tissue will be processed for culture (*Acanthamoeba, Naegleria, Leishmania* spp., *Trypanosoma* spp., or *Toxoplasma gondii*), the specimen should be kept sterile and submitted in a sterile container. If the tissue will be processed for wet examinations and permanent stained smears, any type of container is acceptable. Remember that the specimen must be kept moist; if the specimen dries out during transit, neither culture nor stained smears will provide acceptable results.

2. How should eye specimens be submitted for *Acanthamoeba* culture?

If sending the specimen in a tube/vial or screw-cap tube, make sure the container is filled with transport fluid (saline is acceptable). This will prevent the small tissue specimen from drying out if during transit it is shaken onto the side of the container. If the container is not full of fluid, the tissue may dry out and will be unacceptable for culture.

3. How should duodenal drainage specimens be handled?

Duodenal drainage specimens must be submitted to the laboratory as quickly as possible for processing. Delays may prevent organism recovery and identification. These specimens may be very liquid and may contain a lot of mucus. It is best to centrifuge the tube, discard any supernatant fluid left, and examine the mucus only as wet preparations (low light) and/or permanent stained smears (trichrome, iron hematoxylin). Do not use ethyl acetate in the concentration procedure; a single spin is recommended (do not “rinse” the specimen).

BLOOD PARASITES (1, 2, 13–16; this volume)

Many questions have been asked regarding various aspects of diagnostic medical parasitology and the examination of blood specimens. Answers to these questions may be helpful for those working in this area of microbiology and may provide some “tips of the trade” that are learned through many years of bench experience.

SPECIMEN COLLECTION

Blood

1. If *Plasmodium falciparum* parasites are sequestered in the capillaries, why not do a finger stick rather than a venipuncture?

The capillaries are generally in the deep tissues (spleen, liver, bone marrow), so a finger stick blood sample is no more likely to be positive than venipuncture blood. There may be some minor differences with *P. falciparum*, but not sufficient to warrant eliminating venipunctures. The anticoagulant tube also provides additional blood for multiple thick and thin blood films and/or buffy coat films.

2. What is the best anticoagulant to use for blood specimens?

Although heparin (green top) or EDTA (lavender top) can be used, EDTA is recommended as providing better organism morphology, particularly for *Plasmodium* spp. Blood collected using EDTA anticoagulant is acceptable; however, if the blood remains in the tube for >1 to 2 hours, true stippling may not be visible within the infected RBCs (*Plasmodium vivax*, *Plasmodium ovale*), organism distortion occurs, and **parasite numbers actually decrease after 4 to 6 hours.** Also, when using anticoagulants, the proper ratio between blood and anticoagulant is necessary for good organism morphology. The lavender-top tube should be filled with blood to provide the proper blood-anticoagulant ratio. Heparin can also be used, but EDTA is preferred. Finger-stick blood is recommended when the volume of blood required is minimal (no other hematologic procedures have been ordered). The blood should be free-flowing when taken for smear preparation and should not be contaminated with alcohol used to clean the finger prior to the stick. However, finger stick blood is no longer commonly used in many parts of the world. When blood is collected in EDTA, specimens should be processed immediately after blood collection. **Parasite numbers may decrease if processing is delayed, even 4 to 6 hours.** Adhesion of the blood to the slide can be a problem if the ratio of anticoagulant to blood is high, the patient is anemic, or the blood was held in EDTA too long. See Table A9.2.

3. Why do new slides have to be precleaned with alcohol prior to use?

Even new slides will be coated with a very fine layer of oil (to allow the slides to be "pulled apart" one from the other); removing the greasy coating will cause the blood to flow more smoothly over the glass during blood film preparation. "Holes" in the blood film are evidence of oil or grease on the slide. **Use Standard Precautions:** remember, both slides and spreaders must be held by the edges and not touched on any part of the slide that will come in contact with blood.

4. When should blood specimens be drawn for a suspect malaria diagnosis?

The majority of patients we see in the United States with malaria have never been exposed to the organism before, so they have no antibody. When they are seen in the ER or clinic **they do NOT have a synchronized fever cycle.** These **immunologically naive** patients may present with nonspecific symptoms that can mimic many other diseases. The rule of thumb is to **draw immediately;** do not wait for some "magic" periodic cycle that may never appear. Patients with a very low parasitemia with *P. falciparum* can become quite ill before they have any type of fever cycle or gametocytes. With any patient when malaria is suspect or the patient has an FUO (fever of unknown origin), blood should be drawn and both thick and thin blood films prepared and examined immediately. **This request is always considered a STAT request.** In areas of endemicity where people have been exposed to the parasite before (have some antibody), they may not become symptomatic until they actually have some sort of periodic fever cycle. However, you should always use the general guideline to

TABLE A9.2 *Plasmodium* morphology in EDTA

Organism	Morphology (normal)	Morphology (EDTA) (contact with EDTA for >1–2 hours)
P. falciparum		
Rings	Typical, small to medium rings; double rings/cell	Numbers tend to remain constant; all parasites continue to grow in EDTA
Gametocytes	Crescent-shaped	Gametocytes may round up and be confused with other species
P. vivax		
Trophozoites	Ameboid trophozoites, for both early and late rings	May round up and lose their characteristic shape
Schüffner's dots	Typical dots appear in late rings; present throughout the rest of the life cycle stages	Stippling (Schüffner's dots) may not be visible at all, including all life cycle stages (regardless of buffer pH used) **NOTE**: If slides are prepared soon after collection in EDTA, the dots will be seen after staining; however, if slides are prepared after the blood has been in contact with EDTA for several hours, the dots may not be visible after staining
Plasmodium spp.		
Male gametocytes	No exflagellation	As blood cools and becomes oxygenated, the parasites "think" they are now in the mosquito (this cycle may continue). The male gametocyte may exflagellate; microgametes may resemble *Borrelia* (also related to pH and pCO_2—lid left off tube).

draw immediately. Also, remember that one set of negative blood films does not rule out malaria. If the first set (both thick and thin films) is negative, you can recommend that additional blood films be drawn in about 4 to 6 hours. Also, any decision to delay treatment should be left to the physician, not the laboratory.

SPECIMEN PROCESSING

1. Why is it important that the EDTA blood be processed as quickly as possible?

If a tube of blood containing EDTA cools to room temperature and the cap has been removed, several parasite changes can occur. Due to temperature and CO_2 changes, the parasites within the RBCs will respond as if they were now in the mosquito after being taken in with a blood meal. The morphology of these changes in the life cycle and within the RBCs can cause confusion when examining blood films prepared from this blood.

A. Stippling (Schüffner's dots) may not be visible.
B. The male gametocyte (if present) may exflagellate.
C. The ookinetes of *Plasmodium* species other than *P. falciparum* may develop as if they were in the mosquito and may mimic the crescent-shaped gametocytes of *P. falciparum*.
D. Smears left longer than 24 hours can autofix; if this occurs, lysis of the RBCs will be difficult, if not impossible, to achieve. This tends to occur more quickly in warm, humid climates.
E. Thick smears can be dried in a 37°C incubator for 10 to 15 min without fixation of the RBCs; **do not go beyond 15 min using this method.**

2. Why is it important to keep thick films from getting hot (heat fixation)?

Heat will fix the RBCs, and they subsequently will not lyse in the staining process. (See item E above.)

3. What should you do if you have blood films that can't be stained for several days?

If staining with Giemsa will be delayed for more than 3 days or if the film will be stained with Wright's stain, lyse the RBCs in the thick film by placing the slide in buffered water (pH 7.0 to 7.2) for 10 min, remove it from the water, and place it in a vertical position to air dry. The laked thick films and thin films should be dipped in absolute methanol and placed in a vertical position to air dry. This is particularly important if the blood films will be stored for days or weeks prior to staining. **Processing of patient specimens for diagnosis needs to be performed on a STAT basis; it is inappropriate to hold slides for staining unless they are for teaching purposes and time is not a critical issue. However, the longer the slides are held, the more likely there will be a decrease in overall staining quality.**

DIAGNOSTIC METHODS

1. Why is it important to always examine both thick and thin blood films prior to reporting the specimen as negative for blood parasites?

Thick blood films allow a larger amount of blood to be examined, which increases the possibility of detecting light infections. However, only experienced workers can usually make identifications to the species level from a thick film, particularly for malaria parasites. The morphologic characteristics of blood parasites and identification to the species level are best accomplished from the thin films. However, it is mandatory that both types of films be examined prior to reporting negative findings.

2. What are the advantages of the thick blood film?

The aim of the preparation of a thick film is to have a drop of blood with 20 or 30 layers of RBCs on the slide, then to lyse the red cells, wash off the hemoglobin, and stain the parasites, which remain intact in the process. As a consequence, RBCs will not normally be visible, but WBCs and parasites will be seen. It is essential to get used to the characteristics of malaria parasites and know what to look for on such a preparation. An experienced microscopist should be able to detect 20 parasites per µl of blood (i.e., a parasitemia of 0.0001%), having examined 100 fields in 10 min. A greater volume of blood can be examined in the same amount of time taken for examination of the thin blood film. The presence of phagocytized malaria pigment within WBCs (particularly in cases with low levels of parasitemia) can be very helpful. Occasionally, one can see Schüffner's dots in a thick film. However, recognition of the malarial pigment within WBCs and Schüffner's dots in a thick blood film may be difficult.

3. What are the disadvantages of the thick blood film?

Due to lysis of the RBCs in processing thick blood films, the thick film cannot be used to compare the size of the parasite within the RBC or to compare the size of the infected RBC to the uninfected RBCs. Recognition of organism distortion and identification to the species level are generally more difficult from the thick film.

4. What are some of the problems associated with thick blood films? (17)

The thick film flakes off during the staining process.

a. Film was not dry.
b. Film did not dry evenly.
c. Blood film was too thick (refer to combination thick-thin blood film protocol).
d. The blood was too diluted with anticoagulant or the patient was anemic (centrifuge blood at 500 × *g* for 1 min and repeat the thick film).
e. Slides were greasy or dirty.
f. Blood was in EDTA too long (prepare thick films thinner than normal; dry for a longer period of time).

The thick film does not stain adequately.

g. Blood film was too thick.
h. Staining solution was too dilute or staining time too short.

5. What are some tips for improving thick blood films?

After the thick films are dry, fix the smear with acetone for a few seconds (**only dip twice**) and then air dry the film. This approach will improve the durability of the thick film and will **not** interfere with the lysis of the RBCs. These films tend to have a clean background, making the parasites easier to see. Overall adherence to the slide is enhanced using this approach.

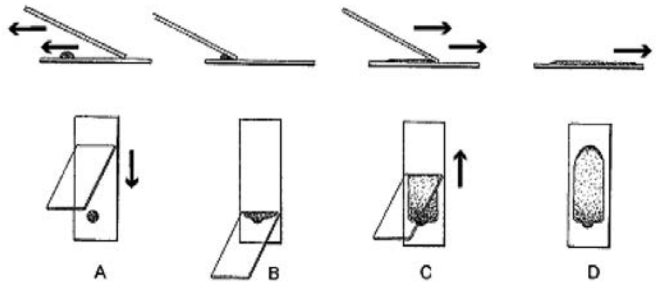

Figure A9.1 The traditional method for preparing a thin blood film. The blood can be either "pushed" or "pulled" by the spreader slide. (Illustration by Sharon Belkin.) Note that "D" illustrates a thin film with a good feather edge. doi:10.1128/9781555819002.Apx9.f1

6. How do you prepare thin blood films?

Keep the spreader at about a 40 to 45° angle to allow blood to flow to **almost the edge of the slide.** Lower the angle to about 30 to 35° to pull the film in one smooth motion (Fig. A9.1). The finished blood film should appear as a feathered edge in the center of the slide, having a **free margin** on either side. Before you fix the thin blood films in absolute methanol, the film must be completely dry. If slides must be stored unfixed, they should be frozen. Fixation too long (>30 to 45 s): stippling may be reduced. Fixation too short: RBCs may be distorted (crescent-shaped) or partially lysed. Fixation: It is better to use a dispensing bottle for methanol, rather than a Coplin jar, in which the methanol will pick up water from the air. Methanol used one day (Coplin jar) should not be reused the next day; begin with fresh stock.

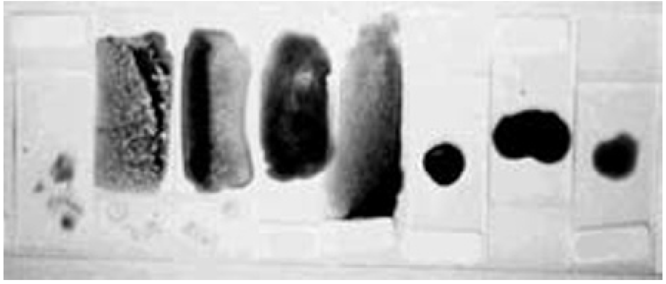
7. What are the advantages of the thin blood film?

The RBC morphology can be seen, as well as the size relationship of the parasite within the infected RBC. The sizes of the infected RBCs can be compared to that of the uninfected RBCs. It is much easier to identify malaria organisms to the species level from the thin blood film. The parasitemia can be much more easily calculated from the thin blood film than the thick film.

8. What are the disadvantages of the thin blood film?

This method has a much lower sensitivity than the thick blood film; thus, infections with a low parasitemia may be missed.

Figure A9.2 Poorly prepared thin and thick blood films (dirty slides, oil on slides, too thick preparations, poor spreading of the blood); organism morphology will be very poor on the stained films. doi:10.1128/9781555819002.Apx9.f2



9. What are some of the problems associated with thin blood films? (Poorly prepared thick and thin blood films can be seen in Fig. A9.2.) (17)

Films are too thick:

a. Too large a drop of blood was used.
b. The RBCs may be crowded together with no thin feathered edge.
c. The film was prepared too quickly or with too large an angle >30 to 35°.

Films are too thin:

d. Blood from anemic patients will not spread well; spread the blood more quickly. Allow the blood to settle or centrifuge, remove some plasma, and repeat the thin film.
e. Angle between the spreader and slide was too small <30°.

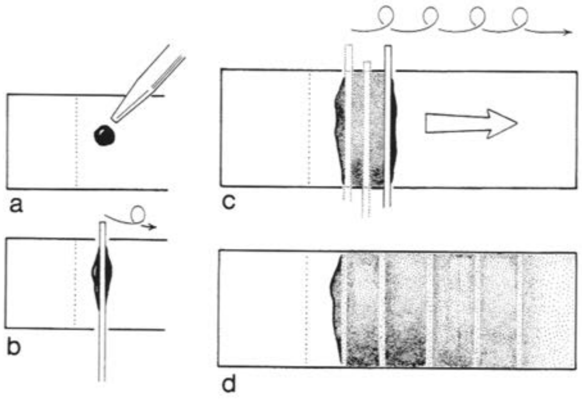
Smears have ragged edges:

f. The drop of blood may have been in front of the spreader.
g. The slides were greasy or dirty.
h. The spreader slide was chipped.
i. The spreader slide was reused (if possible, use a new slide each time).
j. If the blood contained no anticoagulant, a delay in spreading may have led to fibrin formation, causing streaking.
k. May also be due to high plasma fibrinogen level and **not technique.**

10. How does one prepare a combination thick/thin blood film?

The combination thick-thin blood film provides both options on one glass slide, and the slide can be stained as either a thick or thin blood film (Fig. A9.3). If fixed prior to staining, then the

Figure A9.3 Method of thick-thin combination blood film preparation. (a) Position of drop of EDTA-containing blood. (b) Position of the applicator stick in contact with blood and glass slide. (c) Rotation of the applicator stick. (d) Completed thick-thin combination blood film prior to staining. (Illustration by Sharon Belkin.) doi:10.1128/9781555819002.Apx9.f3



smear will be read as a thin blood film; if RBCs are lysed during staining, the preparation will be read as a thick blood film (parasites, platelets, WBCs). This combination blood film dries more rapidly than the traditional thick blood film, thus allowing staining and examination to proceed with very little waiting time for the slide(s) to dry.

A. Place a drop (30 to 40 µl) of blood onto one end of a clean slide about 0.5 in. from the end.

B. Using an applicator stick lying across the glass slide and keeping the applicator in contact with the blood and glass, rotate (do not roll) the stick in a circular motion while moving the stick down the glass slide to the opposite end.

C. The appearance of the blood smear should be alternate thick and thin areas of blood.

D. Immediately place the film over some small print and be sure that the print is just barely readable.

E. Allow the film to air dry horizontally and protected from dust for at least 30 min to 1 hour. Do not attempt to speed the drying process by applying any type of heat, because the heat will fix the RBCs and they subsequently will not lyse in the staining process.

F. This slide can be stained as either a thick or thin blood film.

11. How should malaria smears be stained with Giemsa stain?

Giemsa is a mixture of eosin and methylene blue. Stock solutions of Giemsa may be purchased commercially. Some brands are better than others. The stock solution of Giemsa stain is easily prepared from commercially available Giemsa powder.

Dilutions of Giemsa stain: Stock solutions of Giemsa stain must always be diluted by mixing an appropriate amount of stain with distilled neutral or slightly alkaline water; buffered saline is preferred because it provides a cleaner background and better preservation of parasite morphology. Although most people do not filter the working stain prior to use (if using a Coplin jar), results are better overall if the working stain is filtered through Whatman no. 1 filter paper immediately before use. Make sure to use absolute methanol (acetone-free) for fixing thin blood films. Stock buffered water is stable for 1 year at room temperature. Working stock buffered water is stable for 1 month at room temperature. Stock Giemsa stain is stable at room temperature indefinitely; stock stain appears to improve with age (similar to what is seen with iron-hematoxylin stains). A 45- to 60-min staining time appears to work better than 15 min; staining times will depend on stain dilution. Some workers feel the use of a 10% Triton solution is helpful, while some feel it is detrimental to the overall quality.

12. How should you handle a delay between thick film preparation and staining?

Thick films can be preserved, particularly if there will be a delay prior to staining.

Dip the slides in a buffered methylene blue solution (0.65% for 1 to 2 s and allow the slides to dry.

Methylene blue	0.65 g
Disodium hydrogen phosphate Na_2HPO_4	2.0 g
Potassium dihydrogen phosphate KH_2PO_4	0.65 g
Distilled water	1.0 liter

Mix and store in a brown-stoppered bottle.

The benefits of such an approach are as follows:

a. The RBCs are hemolyzed.
b. Color is introduced into the cytoplasm of the parasites.
c. Prestaining with methylene blue helps preserve the organisms on the smear.

13. Can blood stains other than Giemsa stain be used to stain the blood films?

The detection of parasites in the blood has been made possible by the use of Romanovsky-type differential stains which selectively color the nuclear material red and the cytoplasm blue. This reaction takes place under optimal pH conditions: rather than using a neutral pH, optically perfect results are obtained using the slightly basic pH of 7.2 (due to the optical dominance of red pigmentation). Although for many years, Giemsa stain has been the stain of choice, the parasites can also be seen on blood films stained with Wright's stain, a Wright/Giemsa combination stain, or one of the more rapid stains such as Diff-Quik (American Scientific Products, McGraw Park, IL), Wright's Dip Stat Stain (Medical Chemical Corp., Torrance, CA), or Field's stain. **It is more appropriate to use a stain with which you are familiar, rather than Giemsa, which is somewhat more complicated to use. PMNs will serve as the quality control (QC) organism for any of the blood stains. Any parasites present will stain like the PMNs, regardless of the stain used.** Also, the CAP checklist does not mandate the use of Giemsa stain.

14. How should malaria blood films (both thick and thin films) be examined?

A minimum of 300 oil immersion fields using the 100× objective should be examined. The blood film can be scanned using a 50× or 60× oil immersion lens, but final reporting of the results should be based on the use of the 100× oil immersion lens for a total magnification of ×1,000.

15. What type of QC slides should be used for blood parasite work?

Regardless of the stain you are using (Giemsa, Wright, Wright/Giemsa, rapid stains), **your QC slide is the actual slide you are staining.** This approach to QC is acceptable to CAP, as well. **Any parasites present will stain like WBCs, so your QC is built into the system.**

16. What is a good source for teaching slides?

A good source for teaching slides is Meridian Bioscience, Inc. They have slides and specimens available for sale. Contact them for a brochure: (800) 543-1980, ext. 335.

ORGANISM IDENTIFICATION (1–4; this volume)

1. Why is it so important to "rule out" infections with *Plasmodium falciparum* or *Plasmodium knowlesi*?

P. falciparum causes more serious disease than the other three species (*P. vivax*, *P. ovale*, *and Plasmodium malariae*). *P. falciparum* tends to invade all ages of RBCs, and the proportion of infected cells may exceed 50%. **Also remember that infections**

with *P. knowlesi* are considered as serious as those with *P. falciparum* (24-hour life cycle, heavy parasitemia, all ages of RBCs). Schizogony occurs in the internal organs (spleen, liver, bone marrow, etc.) rather than in the circulating blood. Ischemia caused by the plugging of vessels within these organs by masses of parasitized RBCs will produce various symptoms, depending on the organ involved.

Onset of a *P. falciparum* malaria attack occurs from 8 to 12 days after infection and is preceded by 3 to 4 days of vague symptoms such as aches, pains, headache, fatigue, anorexia, or nausea. The onset is characterized by fever, a more severe headache, and nausea and vomiting, with occasional severe epigastric pain. There may be only a feeling of chilliness at the onset of fever. Periodicity of the cycle will not be established during the early stages, and the presumptive diagnosis may be totally unrelated to a possible malaria infection. If the fever does develop a synchronous cycle, it is usually a cycle of somewhat less than 48 hours. An untreated primary attack of *P. falciparum* malaria usually ends within 2 to 3 weeks. True relapses from the liver do not occur, and after a year, recrudescence is rare. **Severe or fatal complications of *P. falciparum* malaria can occur at any time during the infection and are related to the plugging of vessels in the internal organs, the symptoms depending on the organ(s) involved.** Note: The primary objective when performing blood film examination for parasites is to rule out *P. falciparum* or *P. knowlesi*. It is also becoming more widely recognized that *P. vivax* can cause severe sequelae; this infection is not nearly as benign as previously thought.

2. What are some of the problems associated with the differentiation between *Plasmodium* spp. and *Babesia* spp.? Can *Babesia* spp. cause serious infections?

The ring forms of all four species of *Plasmodium* can mimic the ring forms of *Babesia* spp. Multiple rings per cell are more typical of *P. falciparum* than of the other four species that cause human malaria. *Babesia* rings are often numerous, of smaller sizes, and tend to be very pleomorphic, while those of *P. falciparum* tend to be fewer in number and more consistent in size and shape. Remember that *P. falciparum* rings may appear somewhat larger if the blood has been drawn in EDTA and there is any lag time prior to thick and thin film preparation. Differentiation between *Plasmodium* spp. and *Babesia* spp. may be impossible without examining a thin blood film (rather than a thick blood film). Often, the parasitemia in a *Babesia* infection may be heavier than that seen with *P. falciparum*, particularly when a patient presents early in the infection. It is also important to remember that some of the *Babesia* spp. can cause severe illness (*Babesia divergens* from Europe, etc. [42% mortality], *Babesia* from California, Oregon, Washington, Missouri), while some infections such as those caused by *Babesia microti* cause less serious or subclinical infections. **However, any of the *Babesia* spp. can cause severe disease in immunocompromised patients,** particularly those patients who have undergone splenectomy.

3. What is the significance of finding only ring forms on two sets of blood films drawn 6 hours apart?

Remember that all of the life cycle stages (rings, developing trophozoites, early schizonts, late schizonts, mature schizonts, and gametocytes) can be seen on the blood films in infections with *P. vivax, P. ovale, P. malariae*, and *P. knowlesi*. Due to unique characteristics of the life cycle, only rings and gametocytes (and occasional mature schizonts) are seen in the peripheral blood with a *P. falciparum* infection. **Therefore, if you see two sets of blood films (collected 6 hours apart) that contain ring forms only, there is an excellent chance the patient is infected with *P. falciparum*, the most serious of the five *Plasmodium* spp. infections.**

4. Why aren't gametocytes of *P. falciparum* seen in many patients presenting to the emergency room (ER)?

Many patients present to the ER early in the infection prior to the formation of the gametocytes; thus, the diagnosis must be made based on seeing the ring forms only. As you can imagine, identification of *Plasmodium* to the species level can be very difficult when only rings are present. These patients tend to be travelers who have had no prior exposure to *P. falciparum* (immunologically naive) and who become symptomatic very early after being infected. It normally takes approximately 10 days for the crescent-shaped *P. falciparum* gametocytes to form.

5. What should be considered if the patient has been diagnosed with a *P. falciparum/P. malariae* mixed infection, particularly with a travel history to Malaysia?

P. knowlesi mimics *P. falciparum* early in the infection, while the morphology mimics *P. malariae* later in the cycle. Although relatively uncommon, infections with the fifth human malaria, *P. knowlesi*, are being seen in other parts of the world, primarily in travelers who have been to Malaysia.

REPORTING

1. Why is it important to identify malaria organisms to the species level?

Since *P. falciparum* and *P. knowlesi* can cause severe disease and death, it is very important for the physician to know whether these infections can be ruled out. It is also important to know if any of the other three species are present, particularly *P. vivax* or *P. ovale*, which would require therapy for both the liver and RBC stages due to potential relapse from the liver stages. It is also important because of potential drug resistance (chloroquine, *P. falciparum*, *P. vivax*; primaquine tolerance/resistance, *P. vivax* [rare, but documented]).

2. How should a positive malaria blood film be reported?

A. Using the thin blood film method, report the percentage of parasite-infected RBCs per 100 RBCs counted.

Example: *P. falciparum*, parasitemia = 0.01%

B. Using the thick/thin blood film method, report the number of parasites per microliter of blood.

Example: *P. falciparum*, parasitemia = 10,000/µl of blood

3. How should results be reported if *Plasmodium* spp. parasites are seen, but *P. falciparum* or *P. knowlesi* infection cannot be ruled out?

It is important to convey to the physician that *P. falciparum* or *P. knowlesi* cannot be ruled out; therapy may be initiated on the assumption that this species might be present. The report should read:

Plasmodium spp. present; unable to "rule out" *P. falciparum* or *P. knowlesi.*

4. How often do mixed infections occur, and how should they be reported?

It is important to remember that mixed infections are much more common than suspected and/or reported. When rings are present, along with other developing stages (*P. vivax*, *P. ovale*, *P. malariae*, *P. knowlesi*), always look for the presence of two populations of ring forms, one of which might be *P. falciparum*. The report should read:

Plasmodium spp. present, possible mixed infection; unable to "rule out" *P. falciparum* or *P. knowlesi.*

Another report example might be:

Plasmodium vivax rings, developing schizonts, and gametocytes; possible mixed infection: unable to "rule out" *P. falciparum* or *P. knowlesi.*

5. Why is it important to report the *Plasmodium* spp. stages seen in the blood films?

Often patients who have been diagnosed with *Plasmodium* spp. and are not suspected of having drug-resistant malaria (*P. falciparum*, *P. vivax*) are treated with chloroquine. Chloroquine will not eliminate any gametocytes present, and there are mosquitoes within the United States that can transmit malaria if they take a blood meal from an individual with gametocytes in the blood. Thus, it is important for the physician to know which stages are present in the blood (rings, developing trophs, schizonts, and/or gametocytes).

6. How do parasitemia and malaria severity correlate?

The following percentages are helpful in interpretation of malaria severity:

- Parasitemia of >10,000/µl = heavy infection
- 0.002%, 100/µl, symptomatic below this level
- 0.2%, 10,000/µl, immune patients symptomatic
- 0.1%, 5,000/µl, sensitivity of rapid malaria test (BinaxNOW) at close to 100%; will decrease significantly if parasitemia is below 0.1%
- 2%, 100,000/µl, maximum parasitemia for *P. vivax, P. ovale*; rarely go above 2%
- 2 to 5%, up to 250,000/µl, severe malaria, mortality
- 10%, 500,000/µl, exchange transfusion

PROFICIENCY TESTING

1. How should blood films be examined for proficiency testing (PT)?

Since you have no idea what organisms might be present, always review the blood films using the 10× objective (**entire** slide). This examination is likely to reveal any microfilariae that are present; however, small parasites such as *Plasmodium* and *Babesia* may be missed. Before reporting the smear as negative, examine at least 300 oil immersion fields using the 100× oil immersion objective.

2. Do PT blood films match those seen from actual patients?

Yes and no. Blood films for PT are actual patient specimens, but they may have a higher parasitemia than is seen in many patients reporting to the ER, clinic, etc. Often, smears contain a higher parasitemia than is commonly seen. So the PT smears represent a mix, some of which are fairly typical and some of which have a high number of organisms present. **As in the case of a traveler, the thin blood film may appear to be negative, while the thick film will be positive. In a clinical setting, these blood film results are not that unusual, particularly in an immunologically naive patient (traveler with no prior exposure to *Plasmodium* spp.).**

3. What blood parasites might be seen in PT specimens?

The following parasites may be seen in PT specimens: *P. falciparum*, *P. vivax*, *P. ovale*, *P. malariae*, *P. knowlesi* (less likely) mixed malaria infections, *Babesia* spp., *Trypanosoma cruzi*, *Trypanosoma rhodesiense/gambiense*, *Leishmania* spp., and microfilariae.

GENERAL QUESTIONS

1. What stains are recommended for staining microfilariae?

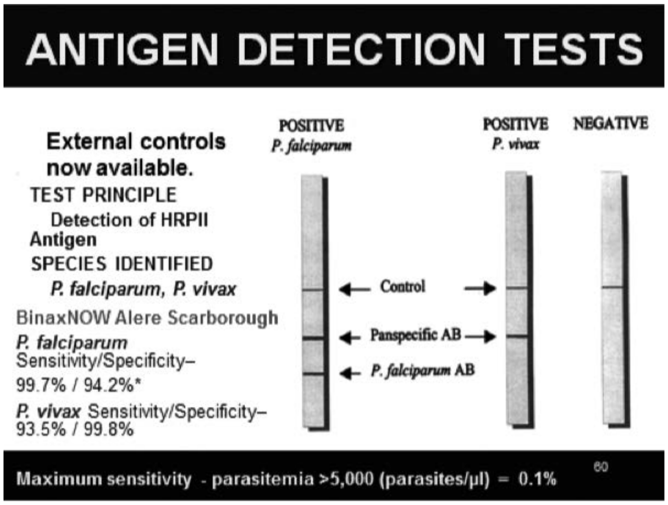
Although Giemsa stain is generally recommended, it will not stain the sheath of *Wuchereria bancrofti*; hematoxylin-based stains (Delafield's) are recommended. Also, the sheath of *Brugia malayi* will stain pink with Giemsa stain.

2. What other methods can be used for the identification of blood parasites?

- Concentrations (trypanosomes, microfilariae, leishmaniae)
- Buffy coat thick and thin blood films (all blood parasites, including *Plasmodium* spp.)
- Skin biopsies or bone marrow aspirates (Giemsa or other blood stains) (leishmaniae)
- Rapid methods/dipstick formats (malaria, microfilariae) (Fig. A9.4; see also Table A9.3). **Note: The Alere/Binax rapid test for *Plasmodium falciparum* and *Plasmodium* spp. is FDA approved (June 2007); a positive external control is also available for customers.** The Binax rapid test is as sensitive as a good microscopist, but often these skilled individuals may not be available on off-hour shifts. However, it is important to recognize the pros and cons of the rapid test when compared to microscopic examination of blood films, particularly in travelers in whom the parasitemia may be considerably less than 0.1%.

3. How good are serologies for malaria; when should they be performed?

Malaria serologies are available through the Centers for Disease Control and Prevention (CDC). They always test with antigens of all five species, but the reactions are not species specific; there is a lot of cross-reactivity. *Plasmodium* spp. can be determined in about 80% of **nonimmune** patients in their **primary** infection (U.S. Army during Vietnam War), but species cannot be determined in patients with long-term exposure and multiple infections (i.e., Africans). The CDC does not recommend serology for identification to the species level; PCR is the best tool for this purpose if pretreatment EDTA blood is available.



ANTIGEN DETECTION TESTS

External controls now available.

TEST PRINCIPLE

Detection of HRPII Antigen

SPECIES IDENTIFIED

P. falciparum, P. vivax

BinaxNOW Alere Scarborough

P. falciparum Sensitivity/Specificity– 99.7% / 94.2%*

P. vivax Sensitivity/Specificity– 93.5% / 99.8%

Maximum sensitivity - parasitemia >5,000 (parasites/µl) = 0.1%

Figure A9.4 General diagram of a rapid malaria test. Readings: top ("Control"), the negative test shows the control line only; middle ("Panspecific AB"), control line plus the *P. vivax* line indicates the presence of a panspecific antigen (common to all *Plasmodium* spp. but most sensitive for *P. vivax* rather than *P. ovale* and *P. malariae*); bottom ("*P. falciparum* AB"), control line, panspecific antigen line, and line specific for *P. falciparum* antigen presence. Note: most cartridge rapid malaria tests have not been developed to detect *P. knowlesi* (under development). See Table A9.3. doi:10.1128/9781555819002.Apx9.f4

4. How do you categorize malaria resistance (seen in both *P. falciparum* and *P. vivax*)?

See Table A9.4.

5. How soon after initiation of therapy for *P. vivax* malaria would one expect to see clearance in blood smears? How soon should follow-up blood smears be submitted for evaluation after therapy?

Although the number of cases we see in the United States is certainly less than in areas of endemicity, we begin to see a drop in parasite numbers very quickly (within a few hours) after the initiation of therapy. If an individual presents in the ER, the parasitemia is often below 1 to 2% (0.1 to 0.01%); the patient is given therapy and is not admitted to the hospital (in the case of *P. vivax*, *P. malariae*, or *P. ovale*). If the organism is identified as *P. falciparum*, *P. knowlesi*, or a mix (most common would be *P. falciparum*/*P. vivax* or *P. malariae*), the patient will be admitted. In some cases, we do not receive blood for follow-up examination (from ER patients where *P. falciparum* and *P. knowlesi* have been ruled out). When treating *P. falciparum*, we receive blood samples approximately every 4 to 6 hours for routine checks (patients will be admitted to the hospital for treatment). Although the number of resistant *P. vivax* cases is small, it has been confirmed, so this is always a consideration, as are mixed infections with *P. falciparum* and *P. vivax*.

6. Where can one get PCR performed for the malaria diagnosis and identification to the species level?

The CDC performs PCR for malaria, which identifies the organisms to the species level. The CDC requires about 0.5 ml of pretreatment EDTA blood. Also, if possible, they like to review both thick and thin smears if extra blood films are available. Specimens can be sent overnight to:

Microbiologist
Division of Parasitic Diseases
Centers for Disease Control and Prevention
Building 109, Room 1302
4770 Buford Highway NE
Atlanta, GA 30341
Phone: 770-488-7044

7. What is the current status of rapid testing for malaria?

This issue has been a difficult one to resolve in the United States. Currently, the Binax rapid test was approved by the FDA in June 2007 (Fig. A9.4) (see Table A9.5). An external positive control is also available for customers. Certainly the use of these rapid tests would be a tremendous advantage for personnel on the night shift. However, **if the test is negative, it would not rule out a *Plasmodium* spp. infection, and thick and thin blood films would need to be prepared and examined STAT.** If positive, then follow-up would need to be performed on slides to rule in/out mixed infections. All published information relevant to these kits indi-

TABLE A9.3 Sensitivity of the Alere BinaxNOW rapid test[a]

Organism	Parasitemia level	% Sensitivity (positive/total)	95% CI
P. falciparum	<5,000	99.7 (326/327)	98–100%
	1,000–5,000	99.2 (126/127)	96–100%
	500–1,000	92.6 (25/27)	76–99%
	100–500	89.2 (33/37)	75–97%
	0–100	53.9 (21/39)	37–70%
Overall		95.3 (531/557)	93–97%
P. vivax	>5,000	93.5 (462/494)	91–96%
	1,000–5,000	81.0 (277/342)	76–85%
	500–1,000	47.4 (37/78)	36–59%
	100–500	23.6 (34/144)	17–31%
	0–100	6.2 (8/129)	3–12%
Overall		68.9 (818/1,187)	66–72%

[a] Parasitemia level of 5,000 = 0.1%. CI, confidence interval.

TABLE A9.4 Categories of malaria resistance

Resistance definition	Comments
Sensitive	From initiation of therapy, asexual parasites are cleared by day 6; no evidence of recrudescence up to day 28. Peripheral blood films appear to go from positive to negative very quickly (can be a change from one draw to the second draw 6 hours later).
Resistance type I (RI)	From initiation of therapy, asexual parasites have cleared for at least 2 consecutive days (the latest day being day 6); recrudescence follows. Parasite count initially drops, and blood films appear to be negative; patient should be monitored for a period of days, particularly if drug-resistant *P. falciparum* is suspected.
Resistance type II (RII)	Within 48 hours of initiation of therapy, marked reduction of asexual parasitemia to <25% of pretreatment count; however, no subsequent disappearance of parasitemia (smear positive on day 6). Patient appears to be improving; parasite count drops, but blood films always appear positive.
Resistance type III (RIII)	Modest reduction in parasitemia may be seen; no change or increase in parasitemia seen during first 48 hours after treatment; no clearing of asexual parasites. In some cases, the parasite count continues to increase with no visible decrease at any time; blood films show overall parasite increase.

cates that they are diagnostically helpful, but they are no better and somewhat less accurate than a good microscopist. However, as we all know, these individuals are often not available during off-hour shifts. Many labs have solved the problem by bringing someone in just to prepare and read slides during off hours. Often, the PM shifts prepare and stain smears (Wright-Giemsa or one of the rapid stains) and another individual examines the thick and thin stained blood films. We tried to expose our residents, postdocs, etc., to these kits and found them to be helpful. **However, when dealing with immunologically naive patients with very low parasitemia values, it would be easy to miss an infection unless careful examination of the thick films was performed. Remember, the rapid test will not take the place of careful examination of both thick and thin blood films.** In other parts of the world, a number of rapid malaria tests are available (15).

8. Can mosquitoes be infected with more than one species of malaria?

There appears to be no barrier to infection of *Anopheles* with mixed *Plasmodium* species. Mosquitoes doubly infected with *P. falciparum* and *P. vivax* were able to transmit both species to humans following deliberate feeding on volunteers (16). In natural situations, however, suppressive effects in the human host may lead to overlapping waves of gametocytes of different species so that there is a tendency for mosquitoes to be infected with only one species. In some cases there may be specific suppression of sporogony of one species compared to the other. For example, in areas where *P. falciparum* and *P. malariae* are sympatric, the cold temperatures associated with altitude may be disadvantageous to *P. falciparum*, which requires a higher temperature

TABLE A9.5 Parasitemia definitions

% Parasitemia	Comments
Parasitemia of >10,000/µl = heavy infection	
0.0001–0.0004, 5–20/µl	Required for a positive thick blood film
0.002%, 100/µl	Immunologically naive patients may be symptomatic below this level
0.02%, 1,000/µl	Can be seen in travelers in ERs (symptomatic very early with low parasitemia = immunologically naive)
0.1%, 5,000/µl	**BinaxNOW rapid lateral flow method** = level of sensitivity below this percentage drops significantly; problem with travelers (0.01% or less)
0.2%, 10,000/µl	Immune patients are symptomatic
2%, 100,000/µl	Maximum parasitemia for *P. vivax* and *P. ovale*; rarely goes >2%
2–5%, up to 250,000/µl	Severe malaria, high mortality
10%, 500,000/µl	Exchange transfusion usually required

for sporogony than *P. malariae*. This may lead to seasonal changes in the prevalence of the two species.

9. What is the general status of PCR for leishmaniasis?

PCR for leishmaniasis has gone through some very rigorous validation at the leishmaniasis lab at Walter Reed Army Institute of Research and is excellent. Contact Dr. Glen Wortmann at glenn.wortmann@us.army.mil.

10. Are serologies available for the African trypanosomes?

The CDC doesn't do PCR for African trypanosomiasis. It is unnecessary for diagnosing *T. b. rhodesiense* (parasites easily detectable by microscopy). PCR for *T. b. gambiense* would need to be arranged by a laboratory in Europe. It is viewed as a research tool only. The CDC consultant is Dr. Anne Moore (770-488-7776).

APPENDIX 10

Current Procedural Terminology (CPT) Codes in Parasitology

Procedure name[a]	CPT
Blood Film (Thick), Blood film stain (includes concentration)	87015 + 87207
Blood Film (Thin), Blood film stain	87207
Buffy Coat Blood Film (Thick), Blood film stain (includes concentration)	87015 + 87207
Buffy Coat Blood Film (Thin), Blood film stain (includes concentration)	87015 + 87207
Calcofluor Stain (direct material, no concentration)	87206
Calcofluor Stain (concentrated material)	87015 + 87206
Concentration, Baermann (plus Wet Mount Examination)	87015 + 87210
Concentration, Blood (Concentration, Wet Mounts) (may be multiple wet mounts prepared/examined—use additional 87210 with modifier) (will include Knott and Membrane Concentrations using Nuclepore filters)	87015 + 87210
Concentration, Harada-Mori (plus Wet Mount Examination)	87015 + 87210
Concentration, Iodine Prep (Wet Prep only)	87015 + 87210
Concentration (Miscellaneous)	87015
Concentration, Petri Dish (plus Wet Mount Examination)	87015 + 87210
Concentration, Saline Prep (Wet Prep only)	87015 + 87210
Counterimmunoelectrophoresis, each antigen (example: *Entamoeba histolytica*)	86185
Cryptosporidium Examination (Modified AFB) (Concentration Sediment)	87015 + 87207
Cryptosporidium Examination (FA) (Concentration Sediment)	87015 + 87272
Cryptosporidium Examination (EIA) (Plate/Tray)	87328
Cryptosporidium Examination (Cartridge)	87328[b]
Cryptosporidium/Giardia Examination (FA) (Concentration Sediment)	87015 + 87272 + 87269
Cryptosporidium/Giardia Examination (EIA) (screen that detects both, but does not differentiate between the two; if positive, separate reagents must be used)	87328 + 87329 (Neg)
Cryptosporidium/Giardia/Entamoeba histolytica/E. dispar group, Cartridge	87328 + 87329 + 87336
Cyclospora Examination (Modified AFB) (Concentration Sediment)	87015 + 87207
Cyclospora Examination (Autofluorescence) (Concentration Sediment)	87015 + 87210
Culture (*Acanthamoeba*) (Agar plates) (Screen, Wet Mount, Permanent Stain) (trichrome, use 87209)	87081 + 87210 + 87207 (Giemsa)
Culture (Intestinal and Blood Protozoa) (Culture, Concentration, Wet Mount, Permanent Stain of culture sediment)	87081 + 87215 + 87210 + 87207 (Giemsa) or 87209 (Trichrome)

Culture, Agar Plate (*Strongyloides*)	87081 + 87210
Culture (*Trichomonas*) (Pouch) (Screen) (microscope exam through plastic pouch)	87081
Ectoparasite Identification (Macro) (Arthropod)	87168
Ectoparasite Identification (Wet Mount) (Arthropod)	87210
Ectoparasite Identification (Skin, Scabies)	87220
Entamoeba histolytica/E. dispar Group (EIA)	87336
Entamoeba histolytica (EIA)	87337
Examination, Wet Prep Only (Wet Prep only)	87210
Examination, Duodenum (Concentration, Wet Mounts)	87177
Examination, Duodenum (Permanent Stain)	87209
Examination, EnteroTest (Wet Mounts only)	87210
Examination, EnteroTest (Permanent Stain only)	87209
Examination, Urine (Random) (Concentration, Wet Mounts) (multiple wet mounts may be prepared/examined—use additional 87210 with modifier)	87015 + 87210
Examination, 24 h Urine (Concentration, Wet Mounts) (multiple wet mounts may be prepared/examined—use additional 87210 with modifier)	87015 + 87210
Fat, Stool (Qualitative)	82705
Giardia Examination (FA) (Concentration Sediment)	87015 + 87269
Giardia Examination (EIA) (Plate/Tray)	87329
Giardia Examination (Cartridge)	87329[b]
Helminth Egg Hatching (Concentration, Wet Mounts)	87177
Isospora (*Cystoisospora*) Examination (Modified AFB) (Concentration Sediment)	87015 + 87207
Leishmania Lesion, Stained Smear	87207
Microsporidia, Special Stain (Modified Trichrome) (on concentration sediment)	87015 + 87207
Microsporidia, Fluorescent Stain (Calcofluor) (on concentration sediment)	87015 + 87206
Occult Blood, Stool	82270
Occult Blood, Gastric	82273
Ova and Parasite Examination (Direct Smears, Concentration and Smears) (also recommended for Concentration and Wet Mounts)	87177
Ova and Parasite Examination (Permanent Stain) (example: trichrome or iron hematoxylin)	87209
Ova and Parasite Examination (Complete Examination) (Direct Smears, Concentration, Permanent Stain)	87177 + 87209
Petri Dish Culture/Concentration (plus Examination)	87015 + 87210
pH, Body Fluid except blood (Stool)	83986
Pinworm Examination, Cellophane Tape	87172
Plasmodium (Parasitemia Determination) Manual Cell Count (RBCs, WBCs, **OR** platelets) each (slide preparation and stain—add separate codes)	85032
Plasmodium (Rapid Tests—dipstick, etc.), infectious agent **antigen** detection by immunoassay with direct optical observation, not otherwise specified T1 = *P. falciparum*; T2 = Pan-malaria band; T3 = Internal control	87899[b] × 3
Reducing Substances, Stool (pH)	83986
Referral In (Stool for Ova and Parasite Exam)	87177 + 87209
Tissue Homogenization for culture	87176
Trichomonas vaginalis, Direct Probe (example: Affirm)	87660
Trichomonas vaginalis, Detection Immunoassay with direct optical observation (example: Osom)	87808
Trypsin Activity, Stool (Qualitative)	84488
Worm Identification (Macro)	87169
Worm Identification (Wet Mount)	87210

---

[a] EIA, enzyme immunoassay; FA, fluorescence assay; AFB, acid-fast bacilli; RBCs, red blood cells; WBCs, white blood cells.

[b] Because there is no analyte code for *Cryptosporidium* or *Giardia* for "immunoassay with direct optical observation" (cartridges), it is appropriate to use the analyte specific code for EIA for the two organisms (for cartridge formats). Since there is a specific code for *Trichomonas* "immunoassay with direct optical observation," this number should be used. **In the coding hierarchy, analyte comes before method.** In the case of the rapid

Plasmodium tests (dipsticks, cartridges), there is no analyte listed for EIA, so in these cases we need to use the nonspecific code: "Infectious agent **antigen** detection by immunoassay with direct optical observation, not otherwise specified" (87899).

NOTES:

When using FA reagents or special stains for the coccidia or microsporidia, you should always perform these tests on centrifuged material, thus the need to add the concentration code 87015.

For multiple specimens or sites per patient per day, use modifier "-91"

> Example: blood for malaria (receipt of more than one specimen/patient/day). This is a repeat of the same test to increase analytical sensitivity.

For repeat laboratory tests performed on the same day/patient, use modifier "-91"

> Example: multiple wet preparation exams for duodenal aspirate (examination of more than one wet preparation from a single specimen per patient per day).

For multiple stool specimens collected on different days, but submitted to the laboratory on one day, code for separate dates (no modifier required).

KEY POINT

When considering a potential audit situation, remember that THE TEST CPT CODES AND BILLS SHOULD MATCH THE SAME TESTS AND BILLS FOR THE TESTS THE PHYSICIAN ORDERED. THEREFORE, IT IS CRITICAL THAT YOUR REQUISITION FORMS AND/OR COMPUTER ORDER SCREENS MATCH WHAT YOU ARE ACTUALLY CODING AND BILLING. This is now an issue since *Giardia* and *Cryptosporidium* (FA, EIA) have now been broken out and should be coded and billed as separate tests.

CPT codes, parasitology, revision 2007 (Immunology, **Antibody** Testing)

Procedure name	CPT
Antibody Detection	
Giardia lamblia	86674
Helminth, not elsewhere specified	86682
Leishmania	86717
Plasmodium	86750
Protozoa, not elsewhere specified (example: *Entamoeba histolytica*)	86753
Toxoplasma	86777
Toxoplasma, IgM	86778
Trichinella	86784
Complement Fixation	
Echinococcosis	86171
Trypanosomiasis	86171
Hemagglutination Inhibition Test (HAI)	
Echinococcosis	86280
Filariasis	86280
Trypanosomiasis	86280
Immunoassay for infectious agent **antibody**, qualitative or semiquantitative, single-step method (e.g., Reagent strip)	86318

Glossary

Certain terms listed here do not appear in the text, but it is hoped that their inclusion will be useful. Diseases and parasites in parentheses represent some, but not all, examples that pertain to the terms listed. One of my favorite definitions is "Parasitologist: A quaint person who seeks truth in strange places" (Schmidt GD, Roberts LS, *Foundations of Parasitology*, CV Mosby Co, St. Louis, MO, 1977).

Abdominal pain Crampy abdominal pain that may be seen in amebic colitis; right upper quadrant pain in amebic abscess; severe duodenitis or jejunitis with *Strongyloides* organisms penetrating the mucosa; pain suggestive of gastric ulcer or appendicitis with anisakid larvae (penetration of gut wall).

Aberrant host One in which the parasite cannot complete its development or appropriate phase of its life cycle.

Aberrant parasite One which is never transmitted from person to person and which develops abnormally in humans (*Echinococcus multilocularis*, *Angiostrongylus*).

Abopercular end In helminth eggs that have an operculum, the opposite end is the abopercular end.

Abscess A localized collection of pus caused by liquefaction necrosis of tissue (amebiasis, filariasis).

Acanthamoebiasis Infection by free-living soil and water amebae of the genus *Acanthamoeba* that may result in a necrotizing dermal or tissue invasion, a fulmination and usually fatal primary amebic meningoencephalitis (PAM), or a subacute or chronic granulomatous amebic encephalitis (GAE).

Acaricide A mite-destroying agent.

Accidental host A host in which the parasite is not commonly found, but which is suitable for the parasite's development. In some instances (e.g., cysticercosis) the accidental host becomes a "dead end" because even though the parasite develops through its appropriate stages, it fails to find a portal of exit and is thus blocked from continuing its life cycle.

Accidental parasite A parasite found in other than its normal host; also called an incidental parasite.

Accolé Early ring form of *Plasmodium falciparum* found at the margin of a red cell: appliqué.

Acetabulum A muscular attachment organ, "sucker" found in helminths.

Acid-fast stain, modified Developed for staining some of the coccidia (*Cryptosporidium*, *Cyclospora*); must be used with gentle decolorizer (1% sulfuric acid recommended).

Acquired immunity Immunity arising from a specific immune response, humoral or cell mediated, stimulated by antigen in the body of the host (active) or in the body of another individual with the antibodies or lymphocytes transferred to the host (passive).

Acute abdomen An abdominal condition of abrupt onset usually associated with abdominal pain resulting from inflammation, perforation, obstruction, infarction, or rupture of intra-abdominal organs; surgical intervention is usually necessary (ascariasis, anisakiasis).

Aerosol A system of respirable particles dispersed in a gas, smoke, or fog that can be retained in the lungs.

AIDS Acquired immune deficiency syndrome.

Alae Pronounced, longitudinal cuticular ridges in nematodes, usually found in larval stages (*Ascaris lumbricoides*), although occasionally present in adult worms (*Enterobius vermicularis*).

Allergy A hypersensitive condition acquired by exposure to a particular allergen (helminth infections, house dust mites, ectoparasite bites or stings).

Amastigote Small, round, intracellular stage of *Leishmania* spp. and *Trypanosoma cruzi* in which the base of the flagellum is anterior to the nucleus but there is no external flagellum; also called Leishman-Donovan body, L-D body, or leishmanial stage.

Anamnestic response Immune response to a challenge or secondary antigen inoculation, marked by a more rapid and stronger manifestation of the immune reaction than after the primary immunizing dose.

Anaphylaxis Hypersensitivity produced by exposure to further doses of the same protein, usually when exposure is within less than 2 weeks (bee stings, echinococcosis).

Anemia A reduced number of erythrocytes per cubic millimeter, reduction in the amount of hemoglobin, or reduction in the volume of packed red blood cells per 100 ml of blood (malaria, hookworm, and *Diphyllobothrium latum* infections).

Anergic Absence of sensitivity to an antigen or the condition resulting from desensitization (cutaneous leishmaniasis).

Aneurysm Circumscribed dilation of an artery connecting directly with the lumen of an artery or a cardiac chamber connecting directly with the lumen of an artery, usually due to an acquired or congenital weakness of the wall of the artery or chamber.

Anorexia Absence of appetite.

Anthropophilic Human-seeing or human-preferring, especially with reference to blood-sucking arthropods.

Anthropozoonosis A zoonosis maintained in nature by animals and transmissible to humans.

Antibodies Proteins (immunoglobulins) found in blood or other body fluids; produced in response to foreign antigens; produced by B cells.

Antigenic determinant The areas on an antigen molecule that bind with antibody or specific receptor sites on the sensitized lymphocyte; these areas determine the specificity of the antibody or lymphocyte.

Antigenic variation An immune evasion strategy used by various parasites; surface antigens are altered from one generation to the next, often as a result of antibody development. (*Trypanosoma* spp.).

Anuria Absence of urine secretion (scorpion sting).

Aphasia Partial or complete inability to speak and/or understand spoken words.

Apoptosis Single deletion of scattered cells by fragmentation into membrane-bound particles, which are phagocytosed by other cells; believed to be due to programmed cell death.

Appendicitis Inflammation of the vermiform appendix (amebiasis, *Ascaris*, *Trichuris*, and *Enterobius* infections).

Appendix Thick-walled fingerlike projection at the end of the cecum.

Appliqué Early ring form of *Plasmodium falciparum* found at the margin of a red cell; accolé.

Artemisinin-based combination therapy A standard antimalarial drug regimen in which artemisinin is taken in combination with one or more other antimalarial drugs.

Ascites Effusion of serous fluid into the abdominal cavity (schistosomiasis).

Aspirate Fluid removed from a cavity or lesion (leishmaniasis, hydatid disease, amebiasis).

Asthma, bronchial Disease characterized by wheezing, coughing, and difficulty in breathing caused by spasmodic contraction of the bronchi; may be the result of allergic reaction (ascariasis, strongyloidiasis, visceral larva migrans, house dust mites). *See* Eosinophilia.

Autochthonous Indigenous or normally found in a particular area.

Autoinfection Reinfection by an organism already present in the body with an increase in the number of parasites without their undergoing a cycle outside the body; self-infection (*Strongyloides stercoralis*, *Hymenolepis nana*, *Cryptosporidium* spp.).

Autopsy Gross and microscopic postmortem examination of the organs of the body to determine the cause of death or pathologic changes.

Avidity Multiple bond interactions; used to describe antibody-antigen interactions; multiple bond binding strength.

Axoneme In flagellates, an internal fibril arising from a blepharoplast and passing through the cytoplasm. An axoneme may leave the body of the flagellate with a small sheath of cytoplasm to become a flagellum or run along the surface of the body lifting the periplast (cell membrane) to form an undulating membrane.

Axostyle Rodlike supporting structure in some flagellates that gives rigidity to the body (*Trichomonas* spp.).

Babesiosis A disease of humans that is caused by a blood protozoan of various animals; tick borne; organism morphology similar to young rings of *Plasmodium falciparum*; more severe in compromised patients.

Band form Older trophozoites of *Plasmodium malariae* and *Plasmodium knowlesi* that may stretch across the red cell in the form of a band.

Barbiero Brazilian term for the blood-sucking hemipteran triatomid bug, *Panstrongylus megistus*, an important vector of Chagas' disease (caused by *Trypanosoma cruzi*).

Basket nucleus Nuclear structure that may be seen in *Iodamoeba bütschlii* cysts (occasionally trophozoites); in well-stained organisms, fibrils may be seen running between the karyosome and the chromatin granules. The "basket of flowers" has been described as follows: the karyosome forms the basket, the fibrils form the stems, and the granules form the flowers.

Baylisascaris A genus of ascarid nematodes found in the intestines of mammals, including humans.

Baylisascaris procyonis A common roundworm of raccoons (ingestion of infective eggs from the environment) that can cause larva migrans (central nervous system). Human cases present with eosinophilic meningoencephalitis (there have been several fatal cases in the United States).

Behçet's syndrome More common in men; involves dermatitis, erythema nodosum, thrombophlebitis, cerebral involvement; may include arthritis, uveitis, or iridocyclitis with hypopyon.

Benign tertian malaria Malaria caused by *Plasmodium vivax*.

Bilharziasis Another name for schistosomiasis; often used to indicate infection with either *Schistosoma mansoni* or *Schistosoma haematobium*.

Binary division (fission) Dividing of a cell into two nearly equal daughter individuals.

Biopsy Removal of tissue from a living person; examination, usually microscopic, used to make diagnosis (Chagas' disease, leishmaniasis, schistosomiasis, visceral larva migrans, amebiasis).

Blackwater fever A condition in which the diagnostic symptom is the passage of reddish to black urine (containing hemoglobin), indicating massive intravascular hemolysis (*Plasmodium falciparum*).

Blepharoplast A small, dark-staining body near the base of the flagellum that is associated with fibrillar portions of the flagellum (blood flagellates).

Botfly Robust, hairy fly of the order *Diptera*, often strikingly marked in black and yellow or gray, whose larvae produce a variety of myiasis conditions in humans and various domestic animals.

Bothrium One of the two shallow grooves on the scolex of *Diphyllobothrium latum*.

Bots The larvae of several species of botflies.

Bradyzoite A slowly multiplying trophozoite contained in the cyst; typical of a chronic infection with *Toxoplasma gondii*.

Buccal cavity/capsule The space between the oral opening and the beginning of the esophagus in nematodes; useful diagnostically in rhabditiform larvae (*Strongyloides stercoralis*, hookworm).

Buccal teeth/plates Toothlike structure in the mouth cavity of the adult hookworms of the genus *Ancylostoma* (in contrast to buccal plates found in the mouth cavity of the genus *Necator*).

Budding Production of daughter cell as outward growth from the original cell or germinal layer (yeastlike fungi, hydatid cyst).

Buffy coat Grayish white layer of fibrin and leukocytes that forms the upper part of the sedimented cells in whole blood after the addition of anticoagulant (examined in visceral leishmaniasis and trypanosomiasis).

Bursa Umbrella-like expansion of the cuticle at the posterior end of male nematodes; it is supported by muscular rays and aids in copulation (hookworms, trichostrongyles).

Cachexia Severe debilitated state (heavy worm infestation, visceral leishmaniasis).

Calabar swellings Transient swellings of subcutaneous tissues; associated with *Loa loa* infection.

Calcareous corpuscles Rounded masses composed of concentric layers of calcium carbonate that are found in the tissue of tapeworms, characteristic of tapeworm tissue; certain fixatives must be avoided to preserve corpuscles for identification purposes (tapeworms).

Calcifications Portions of host or parasite tissue that become hardened by the deposition of calcium salts; may be visible on radiographic studies (toxoplasmosis, cysticercosis, trichinosis, schistosomiasis).

Capitonnage Closure of a cyst cavity by using sutures (hydatid disease).

Capitulum The blood-sucking, probing, sensing, and holdfast mouthparts of a tick, including the basal supporting structure; the relative size and shape of mouthparts forming the capitulum are characteristic for the genera of hard ticks.

Carcinogen Substance capable of causing a malignant tumor in humans or animals.

Carcinoma Malignant tumor from epithelial tissue (*Clonorchis*, *Opisthorchis*, and *Schistosoma* spp.).

Carditis Inflammation of the heart tissues (Chagas' disease).

Carrier A host that harbors a particular pathogen without showing manifestations of disease.

Casoni antigen Skin test antigen composed of sterile hydatid fluid (hydatid disease).

Cathartic A substance causing evacuation of bowels by increasing bulk, stimulating peristalsis.

Cecum A blindly ending appendage of the intestine.

Cell-mediated immunity Type of immunity that is independent of antibody and is initiated by cytotoxic T cells or by the secretion of lymphokines by T cells. The lymphokines cause other cells, usually lymphocytes and macrophages, to aggregate in the area of T-cell–antigen interaction, leading to a local reaction such as a granuloma.

Cercaria Free-living, tailed larval stage of trematodes; may infect humans by direct penetration (schistosomes); may attach to vegetation and encyst to the metacercarial stage (*Fasciola* and *Fasciolopsis* spp.), or may penetrate tissues of vertebrates or invertebrates and encyst to the metacercarial stage (*Clonorchis* spp.).

Cestode Tapeworm.

Chagas' disease Infection caused by *Trypanosoma cruzi* (American trypanosomiasis).

Chagoma Small granuloma in the skin, caused by early multiplication of *Trypanosoma cruzi* (Chagas' disease).

Charcot-Leyden crystals Slender crystals that are formed from the breakdown products of eosinophils; shaped like double, elongated pyramids with pointed ends; can be found in feces, sputum, and tissues; indicates an immune response that may or may not be related to a parasitic infection.

Chiclero ulcer Single, self-limiting cutaneous papule, nodule, or ulcer (usually on the face or ears) (leishmaniasis).

Chigger The six-legged larva of *Trombicula* spp.; a blood-sucking stage of mites that includes the vectors of scrub typhus.

Cholangiocarcinoma Cancer of the bile duct, which can be the result of chronic infections with *Opisthorchis viverrini*, the Southeast Asian liver fluke.

Cholecystitis Inflammation of the gallbladder.

Chorea Irregular, spasmodic, involuntary movements of the limbs or facial muscles.

Chorioretinitis Inflammation of the posterior coat and retina of the eye (toxoplasmosis).

Chromatin Deep-staining DNA-containing portion of the nucleus (protozoa).

Chromatoidal bar/body Deep-staining, bar-shaped, round, or splinter-shaped inclusions found in the cytoplasm of certain amebae (*Entamoeba* spp.).

Chyluria The presence of lymph and emulsified fat in the urine (filariasis).

Cilia Small, hairlike cytoplasmic projections from a cell or organism; used for motility (*Balantidium coli*).

Cirrhosis Disruption of the normal structure of the liver; destruction of liver cells and increase in connective tissue (schistosomiasis).

CLBs These organisms were thought to be a new pathogen, possibly an oocyst, a flagellate, an unsporulated coccidian, a large *Cryptosporidium* sp., a blue-green alga (cyanobacterium-like body), or a coccidian-like body. They are now known to be coccidia in the genus *Cyclospora*.

Coccidian A group of protozoan parasites that infect the epithelial cells of the intestinal tract (and other tissues) (*Cryptosporidium* spp., *Cyclospora cayetanensis*, *Cystoisospora belli*).

Coenurus Tapeworm larva of the genus *Multiceps*, characterized by multiple scolices invaginated into the fluid-filled bladder; no daughter cysts produced.

Colitis Inflammation of the colon.

Colon Portion of the large intestine from the cecum to the rectum.

Coma Absolute unconsciousness.

Commensalism Association in which one individual receives benefits and the other is neither helped nor harmed.

Complement A series of proteins that bind in a complex series of reactions to antibody (immunoglobulin G or M) when the antibody is itself bound to an antigen; produces cell lysis if the antibody is bound to antigens on the cell surface.

Concentration techniques Procedures, usually in fecal examinations, allowing the examination of large amounts of feces (flotation or sedimentation procedures; some available for blood specimens and urine specimens).

Concomitant immunity Type of immunity where the host harbors a population of adult worms but is immune to reinfection.

Congenital Present at, and usually before, birth (regardless of cause).

Conjunctivitis Inflammation of the membrane that lines the eyelids and covers the surface of the eyeball.

Convulsion A violent, involuntary contraction of an extensive group of muscles; disturbance of cerebral function (spider and scorpion envenomation).

Coracidium A ciliated larval tapeworm stage that occurs in the eggs of cestodes such as *Diphyllobothrium* and *Spirometra* spp. (pseudophyllidian tapeworms); this is a free-swimming stage, containing six hooks like those found in the oncospheres of other tapeworms.

Cor pulmonale Cardiopulmonary problems which may terminate in congestive heart failure; obstructive vascular disease (*Schistosoma mansoni* infection).

Corrosive Any substance that causes visible destruction of human tissue at the site of contact. The U.S. Environmental Protection Agency defines corrosivity as a substance that is highly acidic (pH < 2.1) or highly alkaline (pH > 12.4).

Creeping eruption Penetration and migration through subcutaneous tissues by skin-penetrating nematodes, resulting in intense pruritus and sometimes secondary bacterial or fungal infection (*Strongyloides* and hookworm infections, cutaneous larva migrans).

Crithidia Old term for epimastigote.

Cryptosporidiosis Intestinal infection caused by coccidia (*Cryptosporidium* spp.).

Cutaneous Pertaining to the skin.

Cuticle Outermost, three-layered portion of the body wall of nematodes (*Ascaris lumbricoides*, etc.).

Cysticercoid The solid larval stage of tapeworms containing an invaginated scolex that occurs in arthropod intermediate hosts (*Hymenolepis*, *Dipylidium*).

Cysticercosis Tissue infection with larval tapeworms in which the scolex is inverted into a fluid-filled bladder (*Taenia solium*).

Cysticercus Tapeworm larva of the family *Taeniidae* (includes *Taenia solium* and *Taenia saginata*) in which a single scolex is invaginated into a fluid-filled bladder.

Cystoenterostomy Internal drainage of pancreatic cysts into some portion of the intestinal tract (hydatid disease).

Cytoplasm The protoplasm of a cell exclusive of the nuclear material.

Daisy Colloquial term descriptive of the segmented forms (merozoites) of the mature schizont of *Plasmodium malariae*.

Decontamination A procedure that eliminates or reduces microbial or toxic agents to a safe level with respect to the transmission of infection or other adverse affects.

Definitive host Host in which the sexual reproduction of a parasite occurs.

Delayed hypersensitivity A manifestation of cell-mediated immunity, different from immediate hypersensitivity in that the maximal response is reached about 24 h or more after intradermal injection of the antigen; infection site is infiltrated by monocytes and macrophages.

Dermatitis Inflammation of the skin (filariasis, schistosomiasis, infections with *Strongyloides* and hookworm larvae, leishmaniasis, *Sarcoptes* infections).

Diarrhea Frequent passage of soft or liquid stool (no blood); may be caused by any parasite or infection normally found in any part of the intestine (*Giardia lamblia*, *Isospora belli*, *Dientamoeba fragilis*, *Balantidium coli*, *Cryptosporidium* spp., *Enterocytozoon bieneusi*, *Encephalitozoon intestinalis*, possibly other microsporidia, *Cyclospora* spp., *Leishmania* spp. causing visceral leishmaniasis, *Plasmodium falciparum*, tapeworms, *Trichinella* spp., *Schistosoma* spp., hookworm).

Didelphis A genus of marsupials, commonly called opossums, that serve as reservoir hosts of *Trypanosoma cruzi*.

Dioecious Having the male and female sexes of a species as separate individuals.

Direct smear (stool) Approximately 2-mg suspension of fresh, unpreserved feces in water or saline for the purpose of examination for parasites; the primary aim is to see motility.

Disinfectant An agent intended to destroy or irreversibly inactivate all microorganisms, but not necessarily their spores, on inanimate surfaces, e.g., work surfaces or medical devices.

Disseminated infection A parasite enters the body at one point, then disperses throughout the body to other sites.

Diurnal Pertaining to the daylight portion of the 24-h day.

Duodenum The proximal portion of the small intestine (*Strongyloides stercoralis*, *Giardia lamblia*).

Dysentery Frequent watery stools, usually containing blood and/or mucus; associated with inflammation of the intestine, usually the colon (*Entamoeba histolytica*, *Trichuris trichiura*).

Dyspnea Difficulty in breathing.

Dysuria Painful or difficult urination.

Ecosystem The fundamental unit in ecology, comprising the living organisms and the nonliving elements that interact in a defined region.

Ectoparasite Organism that lives on or within the skin of its host (lice, mites, ticks).

Ectopic site Outside the normal location; i.e., the position of a parasite which lodges in an atypical part of the body.

Ectoplasm Outer layer of the cytoplasm of a cell.

Edema Presence of large amounts of fluid, usually in subcutaneous tissues (filariasis, trypanosomiasis, hookworm).

Elephantiasis Inflammation and obstruction of the lymphatic system, resulting in hypertrophy and thickening of the surrounding tissues, usually involving the extremities and external genitalia (filariasis).

Encapsulation Active process of walling off a parasite by the host through the formation of a connective tissue capsule (trichinosis).

Encephalitis Inflammation of the brain (Chagas' disease, trichinosis).

Encystment Formation of a resistant external wall by protozoa to enable them to survive drying and adverse environmental conditions; encysted forms are infective to humans.

Endemic Disease present in a localized community or area at all times.

Endoparasite Parasite that lives within the body of the host.

Endoplasm Inner portion of the cytoplasm of a cell.

Endospore The chitinous inner spore coat (microsporidia).

Engineering controls Controls (e.g., sharps disposal containers, self-sheathing needles, safer medical devices) that isolate or remove a hazard from the workplace.

Eosinophilia Formation of large numbers of eosinophilic leukocytes as a result of some type of immune response; usually found in helminth infections, particularly with tissue invasion (visceral larva migrans, trichinosis, filariasis, schistosomiasis, ascariasis, strongyloidiasis).

Eosinophilic cerebrospinal fluid pleocytosis Increased number of eosinophils in cerebrospinal fluid (*Angiostrongylus* and *Baylisascaris* infections; coenurosis, cysticercosis, echinococcosis, *Fasciola*, *Gnathostoma*, *Paragonimus*, *Schistosoma*, *Toxocara*, *Toxoplasma*, and *Trichinella* infections; possibly *Dirofilaria*, *Onchocerca*, and *Ascaris* infections).

Eosinophilic meningitis Inflammation of membranes of the brain or spinal cord accompanied by an increased number of eosinophils, usually associated with particular helminth infections (angiostrongyliasis, gnathostomiasis, cysticercosis, schistosomiasis).

Epidemic Disease that spreads rapidly and infects many people in a community or area (usually within a short time frame).

Epidemiology The scientific and medical study of the causes and transmission of disease within a population.

Epidermal Pertaining to the outer layer of the skin.

Epididymitis Inflammation of the epididymis (first part of the excretory duct of each testis) (Bancroftian filariasis).

Epimastigote Developmental stage of the family *Trypanosomatidae*; the base of the flagellum is in front of the nucleus, and as the flagellum passes through the body to emerge as the free flagellar portion, it is attached to the body by the undulating membrane. (Old term: crithidia.)

Erythema Diffuse or patchy redness of the skin; blanching on pressure as a result of congestion of cutaneous capillaries.

Erythrocytic cycle Developmental cycle of malarial parasites within the red blood cells.

Eukaryote A cell containing a membrane-bound nucleus with chromosomes of DNA, RNA, and proteins, with cell division involving a form of mitosis in which mitotic spindles (or some microtubule arrangement) are involved; mitochondria are present.

Evagination Protrusion of some part or organ from its normal position (tapeworm scolex in larval worms).

Exflagellation The extrusion of rapidly waving flagellum-like microgametes from microgametocytes; in human malaria parasites, this occurs in the blood meal taken by the proper anopheline vector within a few minutes after ingestion of the infected blood by the mosquito.

Exoerythrocytic cycle A part of the malarial life cycle in which the mosquito introduces sporozoites into the vertebrate host; sporozoites penetrate the parenchymal liver cells and undergo schizogony, resulting in the production of liver merozoites, which then initiate the erythrocytic cycle.

Exospore The proteinaceous outer spore coat (microsporidia).

Facultative parasite One that can complete its life cycle in a free-living environment or, alternatively, that lives during part (or all) of its cycle within a host.

Feces The unabsorbed residue of the digestive process, along with sloughed epithelium, mucus, and bacteria.

Festoon A distinguishing characteristic of certain hard tick species, consisting of small rectangular areas separated by grooves along the posterior margin of the dorsum of both males and females.

Fever A complex physiologic response to disease mediated by pyrogenic cytokines and characterized by a rise in core temperature, generation of acute-phase reactants, and activation of immunologic systems.

Filariform larvae Slender, infective larvae of *Strongyloides stercoralis* and hookworm.

Flame cell Primitive, ciliated excretory cell in trematodes; the movement of the cilia on this cell within the miracidium larva (within a schistosome egg) indicates egg viability.

Flesh flies Members of the order *Diptera*, whose larvae (maggots) develop in putrefying or living tissues.

Fluke Trematode (*Clonorchis*, *Paragonimus*, *Fasciola*, and *Schistosoma* spp.).

Fundus, ocular The portion of the interior of the eyeball around the posterior pole, visible through the ophthalmoscope.

Funiculitis Inflammation of the spermatic cord (filariasis).

Furcocercous Fork-tailed (cercaria of schistosomes).

Gametocyte In malaria, the sexual cell (male microgametocyte or female macrogametocyte). It is present in peripheral blood; fertilization occurs in the mosquito stomach with formation of the zygote.

Gastroenteritis Inflammation of the stomach and small and large intestines.

Genital primordium Ovoid clump of cells that becomes the reproductive system (seen in the rhabditiform larvae of *Strongyloides stercoralis*).

Geohelminth Any helminth that is transmitted to humans from the soil (*Ascaris*, *Strongyloides*, *Trichuris*, hookworm).

Germicide A general term for an agent that kills pathogenic microorganisms on inanimate surfaces.

Granulomatous amebic encephalitis (GAE) *Acanthamoeba* sp. GAE tends to affect immunosuppressed, chronically ill, or otherwise debilitated persons, generally with no particular history of exposure to fresh water sources. Whether caused by an *Acanthamoeba* sp. or *B. mandrillaris*, GAE is a slowly progressive disease of the central nervous system.

Granuloma Tumorlike nodule of firm tissue formed as a reaction to chronic inflammation, usually of lymphoid and epithelioid cells.

Gravid Filled with eggs, such as a gravid pinworm or gravid proglottid of a tapeworm.

Gynecophoral groove or canal The ventral incurved fold of the body extending from the ventral sucker to the caudal extremity, for carrying the female worm (schistosomes).

Halzoun Presence of worms on pharyngeal mucosa; congestion of tissues accompanied by difficulty in breathing and possible asphyxiation (*Fasciola hepatica* and pentastome infection).

Harada-Mori culture Method of incubating fecal material on a filter paper strip in a test tube containing water (cover one-third of the length of paper strip) for the purpose of culturing and recovering nematode larvae (*Strongyloides stercoralis*, hookworm).

Helminth May refer to a nematode (roundworm), cestode (tapeworm), or trematode (fluke).

Hematuria Passage of free hemoglobin in the urine (*Plasmodium falciparum* infection, blackwater fever).

Hemoflagellate Any flagellated protozoan blood parasite (*Trypanosoma* spp.).

Hepatitis Inflammation of the liver (amebiasis, schistosomiasis, infections with liver flukes).

Hepatomegaly Enlargement of the liver.

Hermaphroditism Presence of both male and female reproductive systems in the same individual; most trematodes and cestodes are hermaphroditic.

Heterakis A genus of important nematode parasites. *Heterakis gallinarum* is the cecal worm of chickens and turkeys and is the vector of *Histomonas meleagridis*, a protozoan that causes histomoniasis (a model of the possible transmission of *Dientamoeba fragilis* within helminth eggs such as *Enterobius vermicularis* and *Ascaris lumbricoides*).

Heterophyids Small intestinal flukes parasitic in humans and animals (*Heterophyes* and *Metagonimus* spp.).

Hexacanth embryo Six-hooked tapeworm embryo (oncosphere).

HIV Human immunodeficiency virus.

Hives *See* Urticaria.

HMO Health maintenance organization.

Host An organism in or on which a parasite lives.

Hydatid, alveolar Type of hydatid cyst formed by *Echinococcus multilocularis*; budding is external, as well as internal, and there is no thick outer capsule.

Hydatid, polycystic Type of hydatid cyst formed by *Echinococcus oligarthrus* and *Echinococcus vogeli*; the structure is between those of unilocular and alveolar types of hydatid cyst.

Hydatid, unilocular Type of hydatid cyst formed by *Echinococcus granulosus*; single limiting membrane.

Hydatid cyst Tapeworm larval stage of the genus *Echinococcus*; consists of a large bladder with an inner germinal layer from which daughter cysts and scolices develop (some of which break off and drop into the fluid-filled bladder).

Hydatid sand Consists of scolices, daughter cysts, hooks, and calcareous corpuscles found in the fluid within the hydatid cyst (*Echinococcus granulosus*).

Hydatid thrill A delicate vibration felt by the hand after quick palpation or percussion over the area of the body where the hydatid cyst is located (*Echinococcus granulosus*).

Hydrocele Accumulation of serous fluid in a saclike cavity, particularly the scrotal sac (filariasis).

Hydrocephalus An abnormal accumulation of fluid in the cerebral ventricles or in the subarachnoid space of the brain (cysticercosis).

Hyperparasitemia Infection with *Plasmodium falciparum* at a density of more than 250,000 parasites/μl.

Hyperpigmentation Intensification of pigment; most obvious in dark-skinned races (leishmaniasis, onchocerciasis).

Hypersensitivity Enhanced state of responsiveness following sensitization to a particular antigen. There are four types: type I (anaphylaxis), type II (antibody-dependent cytotoxicity), type III (immune complex hypersensitivity), and type IV (delayed hypersensitivity).

Hypnozoite Exoerythrocytic schizozoite of *Plasmodium vivax* or *Plasmodium ovale* in the human liver, characterized by delayed primary development; responsible for malarial true relapse.

Hypopyon The presence of pus in the anterior chamber of the eye.

Hypostome The central unpaired holdfast organ of the tick capitulum; covered with recurved spines that serve as an anchoring device while the tick feeds.

IATA The International Air Transport Association, a body of the commercial airline industry that governs international aviation. It publishes the *Technical Instructions for the Safe Transport of Dangerous Goods by Air* and regulates dangerous goods for member airlines and anyone who tenders dangerous goods to those airlines.

Immunity The ability of an individual to resist and/or control the effects of antigens (antigen sources could be animal, plant, or mineral).

Immunoglobulin A (IgA) A class of immunoglobulin that is the second most common immunoglobulin in blood. It is the main immunoglobulin found in secretions, such as tears, saliva, colostrum, mucous membranes of the intestine, respiratory and reproductive tracts. IgA provides local defense against microorganisms as they try to infect mucous membranes.

Immunoglobulin E (IgE) A class of immunoglobulin that is concentrated in the lungs, skin, and mucous membranes. It provides the primary defense against environmental antigens and reacts with certain antigens to trigger the release of chemical mediators that cause anaphylactic hypersensitivity reactions characterized by wheal and flare; may indicate a parasitic infection.

Immunoglobulin G (IgG) This is the most abundant immunoglobulin and is approximately equally distributed in blood and in tissue liquids. Approximately 75% of serum immunoglobulins in humans is IgG.

Immunoglobulin M (IgM) This is the third most common immunoglobulin in serum. IgM is the first class of immunoglobulin that is produced by immune cells when stimulated by antigen.

Immunologically naive An individual who has not been exposed to a particular parasitic antigen; often used to refer to patients who may have malaria for the first time and have no residual antibody (*Plasmodium* spp. in travelers).

Incubation period Time span from introduction of disease-causing organisms until symptoms of the disease occur.

Induced malaria Malaria infection acquired by blood transfusions or possible sharing of needles by drug addicts (*Plasmodium* spp.).

Infectious waste Waste containing or assumed to contain pathogens of sufficient virulence and quantity that exposure to the waste by a susceptible host may result in a communicable disease.

Infestation Presence of arthropods on the surface of the body; does not refer to endoparasites (*Pediculus* spp.).

Inflammation Result of tissue reaction to injury; symptoms are redness, pain, swelling, and fever.

Innate immunity Inborn resistance mechanisms that are encountered by a pathogen, before adaptive immunity is induced.

Inspissate To thicken or dry a substance by removing liquids by evaporation (preparation of certain types of media used to grow some amebae).

Intermediate host A required host in the life cycle in which larval development takes place; this must occur before the stage is infective for the definitive host or secondary intermediate hosts.

Invagination The ensheathing, enfolding, or insertion of a structure within itself or another (tapeworm larval worms).

Jaundice A condition caused by excess bilirubin and bile pigment deposition in the skin, which may give the patient a yellow appearance, especially the eyes (*Plasmodium falciparum*).

The Joint Commission Formerly the Joint Commission on Accreditation of Healthcare Organizations (JCAHO). An independent, not-for-profit organization, The Joint Commission accredits and certifies more than 20,500 health care organizations and programs in the United States. Joint Commission accreditation and certification are recognized nationwide as a symbol of quality that reflects an organization's commitment to meeting certain performance standards.

Kala azar Another name for visceral leishmaniasis (*Leishmania donovani*).

Karyosome Concentrated clumps of chromatin material within the nucleus; position and morphology are often used to differentiate intestinal protozoa.

Kerandel's sign Delayed sensation to pain (African trypanosomiasis).

Keratitis Inflammation of the cornea (Chagas' disease, onchocerciasis, *Acanthamoeba* infection, microsporidiosis).

Keratoconjunctivitis Inflammation of the conjunctiva and of the cornea.

Kinetoplast Intensely staining rod- or disk-shaped or spherical extranuclear DNA structure found in parasitic flagellates near the base of the flagellum.

Knott technique Concentration procedure using blood and dilute formalin; designed to detect microfilaria (*Wuchereria* and *Brugia* spp.).

Kupffer cells Phagocytic epithelial cells lining the sinusoids of the liver.

Lagochilascaris minor An unusual nematode parasite of humans (ingestion of infective eggs from the environment or ingestion of infective larvae in the tissues of an intermediate host). In most cases, the worms are located in the soft tissues of the neck and throat, tonsils, mastoids, and paranasal sinuses (chronic or recurrent abscesses). Fatal encephalopathy (one case) has also been reported. All cases were in the tropical regions of the Western Hemisphere.

Larva currens Cutaneous larva migrans caused by rapidly moving larvae of *Strongyloides stercoralis*, typically extending from the anal area down the upper thighs; may also be caused by zoonotic species of *Strongyloides*.

Larva migrans, cutaneous/visceral/ocular/neural Disease characterized by thin, red, convoluted papular or vesicular lines of eruption that extend at one end while fading at the other (dog or cat hookworm). Visceral larva migrans involves migration of larvae through the deep tissues, including the eye (dog or cat ascarids, *Toxocara* spp.). The central nervous system may also be involved.

Latex allergy Allergic reaction associated with latex glove use. The two types of allergic reactions are contact dermatitis (type IV delayed hypersensitivity) due to chemicals used in processing latex and the more serious IgE/histamine-mediated allergy (immediate or type I hypersensitivity) due to latex proteins.

Leishman-Donovan body Small, round, intracellular form of *Leishmania* spp. (reticuloendothelial system) and *Trypanosoma cruzi* (striated muscle); also called amastigotes or L-D bodies.

Leptomonad Old term for the promastigote stage, which is long and slender and found in the insect vector for *Leishmania* spp.; it is also recovered in artificial culture media (Novy-MacNeal-Nicolle [NNN] medium).

Leukocytosis Increase in the number of white blood cells, usually to more than 10,000/mm^3.

Leukopenia Decrease in the number of white blood cells, usually to less than 4,000/mm^3.

Lichen simplex A discrete flat papule or an aggregate of papules giving a patterned configuration resembling lichens growing on rocks.

Loeffler's syndrome Transient pulmonary infiltration; day-to-day clearing in 3 to 14 days; associated with marked peripheral eosinophilia (*Ascaris lumbricoides*) (also Loffler's, Löffler's).

Lumen Cavity of hollow, tubular organs, such as the intestine or blood vessels.

Lymph Plasma and white blood cells that bathe the tissue cells.

Lymphadenitis Inflammation of the lymph nodes (filariasis).

Lymphangitis Inflammation of the lymphatic vessels (filariasis).

Lymphedema Swelling from excess fluid due to malfunction of the lymphatic system.

Lymphocytosis Absolute or relative increase of lymphocytes in the blood.

Lymphokine One of several kinds of effector molecules released by T lymphocytes when an antigen to which the lymphocytes are sensitized binds to the cell surface.

Lymph varices Dilated lymph vessels secondary to lymphatic blockage (filariasis).

Macrogametocyte The mother cell producing the macrogametes, or female elements of sexual reproduction in the sporozoan and microsporidian protozoa; macrogamont.

Macronucleus Large, kidney bean–shaped nucleus in *Balantidium coli* (the shape is not always consistent).

Macrophage Motile, phagocytic, mononuclear cell that originates in the tissues and may be confused morphologically with protozoan trophozoites (particularly *Entamoeba* spp.).

Malabsorption Poor fat absorption in the upper small bowel (giardiasis).

Malaise Vague feeling of discomfort throughout the whole body; tiredness.

Malaria Benign tertian malaria, *Plasmodium vivax*; malignant tertian malaria, *Plasmodium falciparum*; ovale malaria, *Plasmodium ovale*; quartan malaria, *Plasmodium malariae*; simian malaria, *Plasmodium knowlesi*; relapsing malaria, renewal of clinical activity at some interval after the primary attack; remittent malaria, a malarial fever (usually due to *P. falciparum*) in which the temperature falls but not to the normal level during the interval between two pronounced paroxysms.

Malarial pigment Composed of hematin and excess protein left over from the metabolism of hemoglobin; appears as brownish pigment after Giemsa staining (*Plasmodium* spp.).

Malignant tertian malaria Malaria caused by *Plasmodium falciparum*.

Mast cell A connective tissue cell that contains coarse, basophilic, metachromatic granules; the cell is thought to contain heparin and histamine.

Mastocytosis Abnormal proliferation of mast cells in a variety of tissues; may be systemic, involving a variety of organs, or cutaneous (urticaria pigmentosa).

Maurer's dots or clefts Irregular dots that occur infrequently in red blood cells infected with *Plasmodium falciparum* (dots tend to be more blue after Giemsa staining than do Schüffner's dots).

Measly Pertaining to pork or beef infected with the cysticerci of the tapeworms *Taenia solium* or *Taenia saginata*.

Megacolon Dilation of the colon (Chagas' disease).

Megaesophagus Dilation of the esophagus (Chagas' disease).

Meningitis Inflammation of the membranes of the brain or spinal cord.

Meningoencephalitis Inflammation of the brain and its surrounding membranes (trypanosomiasis, malaria, *Naegleria* and *Angiostrongylus cantonensis* infections).

Merogony Synonym for schizogony, leading to the production of daughter cells (merozoites).

Meront Diplokaryotic cells that grow and divide into daughter cells (merozoites).

Merozoite Product of schizogonic cycle in malaria; produced in the liver (pre-erythrocytic cycle) and in the red blood cells (erythrocytic cycle).

Mesentery Tissue that supports the intestinal tract.

Metacercaria The infective, encysted larval form of a trematode; found within the tissues of an intermediate host or on plant material (*Paragonimus*, *Clonorchis*, and *Fasciolopsis* spp.).

Methenamine silver stain Both hot and cold methods; involves deposition of silver onto cyst wall (*Pneumocystis jiroveci* [now classified with the fungi]).

Microfilaria Embryos produced by filarial worms (nematodes); usually found in the blood or tissues of patients with filariasis (*Wuchereria*, *Brugia*, and *Onchocerca* spp.).

Microgametocyte The mother cell producing the microgametes, or male elements of sexual reproduction in the sporozoan and microsporidian protozoa; microgamont.

Micrometer (micron) Unit of measure equal to 0.001 mm; abbreviated µm.

Micron *See* Micrometer.

Micronucleus Small, dotlike nucleus found in *Balantidium coli*; often very difficult to see, even in stained preparations.

Miracidium Free-living, ciliated larva released from a trematode egg and infective for the snail intermediate host.

Monocytosis Increase in the number of monocytes in the peripheral blood; may be found in both helminth and protozoan infections.

Monoecious Both male and female reproductive organs occur in the same individual (hermaphroditic) (trematodes, cestodes).

Montenegro test Delayed-hypersensitivity skin test; injection of leishmanial antigen; read after 72 h; positive reaction in cured individuals, negative in early cases (visceral and mucocutaneous leishmaniasis).

Mordant A substance capable of combining with a dye and the material to be dyed, thereby increasing the affinity or binding of the dye.

MSDS Material Safety Data Sheet Provides detailed information about hazards and protective measures relative to a hazardous chemical substance.

Multilocular cyst Cyst containing many cavities (*Echinococcus multilocularis*).

Mutualism Association in which both parties benefit and cannot survive without each other.

Myiasis Infestation with maggots (fly larvae).

Myocarditis Inflammation of the heart muscles (trichinosis, trypanosomiasis, toxoplasmosis).

Myositis Inflammation of voluntary muscles (trichinosis, *Sarcocystis* infections).

Nanophyetus salmincola Digenetic trematode that causes infections in humans (ingestion of raw, undercooked, or smoked salmon); infections have been reported from North America. Symptoms include gastrointestinal complaints, unexplained eosinophilia, and recovery of eggs from stool specimens.

Necropsy *See* Autopsy.

Negative predictive value (NPV) (Example) The probability that the individual is not infected by *Plasmodium* when the rapid test is negative.

Nit The ovum or hatched egg of a body, head, or crab louse; it is attached to human hair or clothing by a layer of chitin.

Nocturnal Pertaining to the dark portion of a 24-h day; active at night (filariasis).

Nodule A small, hard node that can be detected by touch (onchocerciasis, coenurosis, cysticercosis, myiasis).

Nucleophaga A microsporan parasite of amebae that destroys the nucleus of its host.

Nucleus A cellular inclusion composed of chromatin; the morphology is often used to help identify intestinal protozoa (*Entamoeba* and *Dientamoeba* spp.).

Obligate parasite Parasite that must always live in contact with the host.

Occult blood Blood present in very small amounts; usually detectable only by chemical means. The specimen is usually a stool sample. The finding may or may not be related to parasitic infection.

Occupational exposure Reasonably anticipated skin, eye, mucous membrane, or parenteral contact with a hazard that may result from the performance of an employee's duties.

Omentoplasty Use of the greater omentum to cover or fill a defect (hydatid disease).

Onchocercoma Nodule containing adult worms (onchocerciasis).

Oncosphere Spherical, six-hooked tapeworm larva within the eggshell (*Taenia* and *Hymenolepis* spp.).

Oocyst A thick- or thin-walled stage in the life cycle of the coccidia. Stage shed in feces in human infections.

Ookinete The motile zygotes of the malarial parasite that penetrate the mosquito stomach to form an oocyst under the outer gut lining. In an opened tube of human blood, this stage can develop over time as the blood cools and is oxygenated (the malarial parasites "think" they are in the mosquito, and exflagellation and development of the ookinete can occur within the tube of blood; this is not common but is well documented, and the morphology can mimic the *Plasmodium falciparum* gametocyte).

Operculate egg Egg with a lid (trapdoor) at one end through which the larva escapes (*Diphyllobothrium*, *Clonorchis*, and *Paragonimus* spp.).

Operculum A lidlike structure at one end of the egg shell through which the larval form escapes (*Diphyllobothrium*, *Clonorchis*, and *Paragonimus* spp.).

OPIM *See* Other potentially infectious material.

Opportunistic Denoting an organism capable of causing disease only in a host whose resistance is lowered (by other diseases or drugs, etc.); also denotes the disease.

Opsonization Modification of the surface characteristics of an invading particle or organism by binding with antibody or a nonspecific molecule to facilitate phagocytosis by host cells.

Orchitis Inflammation of a testis; may be accompanied by swelling, pain, and fever (filariasis).

OSHA Occupational Safety and Health Administration.

Other potentially infectious material (OPIM) Human body fluids including semen, vaginal secretions, urine, cerebrospinal fluid, synovial fluid, pleural fluid, pericardial fluid, peritoneal fluid, amniotic fluid, saliva, body fluids which may be contaminated with blood, unfixed tissue, HIV- or hepatitis virus–containing cell or organ cultures, blood and tissue from an infected animal, reagents, infectious waste, and cultures.

Oviparous Egg-laying.

Pancytopenia Pronounced reduction in the number of erythrocytes, all types of white blood cells and blood platelets in the circulating blood.

Pan-malarial antigen An antigen expressed by all five of the *Plasmodium* spp. which are pathogenic in humans, i.e., *Plasmodium falciparum*, *Plasmodium vivax*, *Plasmodium malariae*, *Plasmodium ovale*, and *Plasmodium knowlesi*.

Papule Small, solid elevation of the skin.

Parasite An organism living on or in, and at the expense of, another organism.

Parasitemia The presence of parasites in the circulating blood (malaria, trypanosomes, microfilariae).

Parasitophorous vacuole Extracellular but intracytoplasmic vacuole, surrounded by host cell membrane (*Cryptosporidium*).

Paratenic host A host in which a parasite survives without undergoing any additional development (a transport host only) (e.g., *Lagochilascaris minor*).

Parenteral Piercing mucous membranes or the skin through such events as needlesticks, human bites, and abrasions.

Paresis Slight paralysis (cysticercosis).

Paroxysm Rapid onset or return of symptoms or increased intensity of symptoms; usually applies to the periodicity of malaria symptoms (chills, fever, sweats).

Parthenogenesis Form of sexual reproduction in which the organism develops without fertilization by the male gamete (*Strongyloides stercoralis,* parasitic generation).

Patency The development stage at which helminths begin egg production; time to maturity (intestinal helminths).

Pathogen Any organism or substance that produces a disease state.

Pemphigus Autoimmune bullous diseases; nonspecific term for blistering skin diseases.

Pentatrichomonas A genus of parasitic protozoan flagellates, formerly part of the genus *Trichomonas*. New generic name for *Trichomonas hominis,* a nonpathogenic flagellate living in the human colon.

Pericardial tamponade Condition resulting from accumulation of excess fluid in the pericardium.

Periodic acid-Schiff stain (PAS) Involves an oxidation process by periodic acid followed by Schiff reagent (detection of newly formed aldehyde groups) and sulfurous rinses; glycogen, chitin, and mucoproteins are strongly PAS positive; lipids are PAS positive (amebae, worm cuticle, part of microsporidial spore, fungi).

Periodicity Recurrence of an event at regular intervals (nocturnal periodicity of microfilariae of *Wuchereria bancrofti;* malarial symptoms).

Peristalsis Movement of food through the intestine by contractions of the intestinal musculature.

Peritonitis Inflammation of the membrane that lines the abdominal cavity and covers the viscera.

Permissible exposure limit (PEL) Maximum allowed exposure during a time-weighted average (8-h workday or 40-h workweek).

Personal protective equipment (PPE) Specialized clothing or equipment worn by an employee for protection against a hazard.

Petechiae Minute, hemorrhagic spots in the skin or mucosa.

Pica A craving for substances not fit for food, such as starch, clay, ashes, or plaster; ingestion of clay or soil can be associated with exposure to *Ascaris*, *Trichuris*, hookworm, *Strongyloides*, *Toxocara*, and *Toxoplasma* organisms.

Pinworm Human roundworm parasite of the colon and rectum, extremely common in children; diagnostic approach is with a Scotch tape preparation (*Enterobius vermicularis*).

Pipe-stem fibrosis Granulomatous reaction around schistosome eggs in periportal tissues; fibrous tissue is white and hard (*Schistosoma japonicum*, *Schistosoma mansoni*).

Plasma Liquid portion of the blood or lymph.

Plerocercoid Tapeworm larva of the genera *Diphyllobothrium* and *Spirometra*; also known as a sparganum larva.

Pneumonitis Inflammation of the pulmonary tissue (*Ascaris*, *Strongyloides*, *Pneumocystis* spp.).

Polar filament (microsporidia) A thin tubule within the spore, attached anteriorly, extending back and lying coiled within the spore; part of the extrusion apparatus that everts and inoculates the sporoplasm into a host cell (microsporidia); same as polar tubule.

Polar filaments (*Hymenolepis nana*) Filaments arising from opposite poles of the oncosphere membrane of *H. nana;* they lie between the egg shell and the oncosphere.

Polar plugs Mucoid plugs present at both ends of the egg (*Trichuris trichiura*).

Polymerase chain reaction (PCR) a technique used to make numerous copies of a specific segment of DNA (or RNA) quickly and accurately.

Positive predictive value (PPV) (Example) The probability that an individual actually is infected by *Plasmodium* when the rapid test is positive.

Prepatent period Time between infection of the host and the beginning of egg production (intestinal helminths).

Primary amebic meningoencephalitis (PAM) An invasive, rapidly fatal cerebral infection by soil and water amebae, chiefly *Naegleria fowleri*, found in humans and other primates. The disease is characterized by high fever, neck rigidity, and symptoms associated with upper respiratory infection (cough and nausea). The brain is the primary focus, especially the olfactory lobes and cerebral cortex; organisms enter through the nasal mucosa and through the cribriform plate. Death usually occurs 2 to 3 days after onset of symptoms.

Primary container A vessel, including its closure, which contains the specimen.

Prions Infectious, abnormal host proteins that cause transmissible spongiform encephalopathies and are resistant to a number of standard disinfection and sterilization procedures.

Proglottid Tapeworm segments containing male and female reproductive systems; may be immature, mature, or gravid (*Taenia* and *Hymenolepis* spp.).

Promastigote Development stage of the family *Trypanosomatidae*; the base of the flagellum is anterior to the nucleus, the free flagellar portion is short, and there is no undulating membrane.

Prophylaxis The use of drugs in healthy individuals to prevent initial infection (*Plasmodium* spp).

Proteinuria Protein in the urine (*Plasmodium falciparum*).

Protozoa Single-celled eukaryotes (organisms whose cells have nuclei) that that are primarily unicellular, existing singly or aggregating into colonies, are usually nonphotosynthetic, and are often classified further into phyla according to their capacity for and means of motility, as by pseudopods, flagella, or cilia.

Prurigo nodularis An eruption of hard nodules in the skin, caused by rubbing and accompanied by intense itching.

Pruritus Severe itching (cutaneous larva migrans, infection with scabies, itch mite, or pinworm).

Pseudocyst Usually refers to a large number of *Toxoplasma gondii* trophozoites enclosed in a macrophage or some other host cell; parasites bound by host cell tissue not of parasite origin.

Pyrogenic Producing fever.

Pyuria Presence of pus (bacteria, white blood cells) in the urine.

Quartan malaria Malaria caused by *Plasmodium malariae*.

Quotidian malaria Type of malaria in which fevers occur every 24 h; may indicate early infection or mixed infection.

Rash A superficial skin eruption; may be macular, maculopapular, blotchy, etc.

Rectal prolapse Extrusion of the rectal mucosa through the anus; may occur in children with heavy *Trichuris trichiura* infections. Usually no sequelae after therapy.

Rediae An elongated sac with a mouth, muscular pharynx, primitive gut, birth pore, and germinal cells, which may develop into cercariae or daughter rediae (stage within snail host: trematodes).

Regulated waste Liquid or semiliquid blood or OPIMs; contaminated items that would release blood or OPIMs in a liquid or semiliquid state if compressed; items that are caked with dried blood or OPIMs and are capable of releasing these materials during handling; contaminated sharps; and pathological and microbiological wastes containing blood or OPIMs.

Reservoir host The host of an infection in which the infectious agent multiplies and/or develops and on which the agent is dependent for survival in nature; essential host for maintenance of the infection when active transmission is not occurring.

Retinochoroiditis Inflammation of both the retina and the choroid/vascular coat of the eye (toxoplasmosis, onchocerciasis, visceral larva migrans).

Rhabditoid (rhabditiform) larvae Noninfective, thick, rod-shaped larvae of hookworm and *Strongyloides stercoralis*; rhabditoid refers to the shape of the larval esophagus.

Romaña's sign Marked edema of one or both eyes; usually dry and unilateral (Chagas' disease).

Rosette Arrangement of merozoites in mature schizont of *Plasmodium malariae* in a circle around a clump of excess pigment; also the uterine arrangement in the *Diphyllobothrium latum* proglottid.

Rostellum The anterior fixed or invertible portion of the scolex of a tapeworm, frequently provided with a row (or several rows) of hooklets ("armed rostellum") (*Taenia solium*).

Sappinia diploidea A newly recognized human pathogen causing amebic encephalitis.

Scabies An eruption due to the mite *Sarcoptes scabiei*; the female burrows into the skin, producing a vesicular eruption with intense pruritus between the fingers, on the male genitalia, buttocks, and elsewhere on the trunk and extremities. Crusted scabies is a severe form of scabies with innumerable mites in thickened stratus corneum. This infection has been linked with cellular immune deficiencies, including AIDS.

Schizogony A stage in the asexual cycle of the malarial parasite that occurs within the red blood cells; results in the formation of merozoites (*Plasmodium* spp.).

Schüffner's dots Tiny, red-staining granules in the cytoplasm of red blood cells infected with either *Plasmodium vivax* or *P. ovale*; true stippling (with Giemsa stain).

Scolex The head or attachment portion of a tapeworm; attachment may be by suckers or hooklets (*Taenia*, *Diphyllobothrium*, and *Hymenolepis* spp.).

Scutum In hard ticks, a plate that largely or entirely covers the dorsum of the male and forms an anterior shield behind the capitulum of the female or immature ticks.

Seatworm Another name for pinworm (*Enterobius vermicularis*).

Secondary container A vessel into which the primary container is placed for transport within an institution; it will contain a specimen if the primary container breaks or leaks in transit.

Segmentectomy Excision of a segment of an organ or gland (hydatid disease).

Sensitivity The proportion of true positives that are correctly identified by a test.

Sharps container A container approved for the transport of contaminated sharps.

Sheath Cuticle of a larval nematode that is retained around the body; may serve as protection. Used to help identify microfilariae (*Wuchereria* and *Brugia* spp., *Loa loa*).

Shock Marked decrease in blood pressure; rapid pulse, decreased kidney function (*Plasmodium falciparum* malaria, rupture of hydatid cyst, bee stings).

Short-term exposure limit (STEL) Maximum permitted continuous exposure to a hazardous substance (normally measured in a single 15-min period).

Sigmoidoscopy Visual examination of the rectum and sigmoid flexure of the colon with a lighted tube; often performed for suspected amebiasis cases (*Entamoeba histolytica*).

Simian malaria *Plasmodium knowlesi*.

Sinusitis Inflammation of the sinuses.

Sparganum A migrating tapeworm larva that invades the subcutaneous tissues, causing inflammation and fibrosis (*Diphyllobothrium* and *Spirometra* spp.).

Specificity The proportion of true negatives that are correctly identified by a test.

Spicule Accessory reproductive structure in male nematodes; useful in identification of species.

Spiracle A breathing aperture in arthropods.

Splenomegaly Enlargement of the spleen (leishmaniasis, schistosomiasis, malaria).

Splinter hemorrhages Effects of vasculitis in trichinosis; tiny linear hemorrhages in nail beds (larval migration).

Spore One of the stages in the life cycle of the microsporidia; contains a polar tubule apparatus used for infecting cells; the number of polar tubule coils in the spore is used in organism classification.

Sporocyst An elongated sac without a mouth or other distinct internal or external structure, formed after a miracidium infects a snail. May give rise to cercariae (schistosomes) or rediae (*Paragonimus* spp.).

Sporogony (microsporidia) Production of spores.

Sporogony (*Plasmodium*) A stage in the sexual cycle in the malarial parasite that takes place in the mosquito, with eventual production of the infective sporozoites.

Sporont The zygote stage within the oocyst wall in coccidia; gives rise to sporoblasts, which form sporocysts, within which the infective sporozoites are produced.

Sporozoite Slender, spindle-shaped organism that is the infective stage of malaria parasites; inoculated into humans by the bite of an infected female mosquito; the result of the sexual cycle in the mosquito.

Sporulation The development of spores; a unit of asexual reproduction that may be adapted for dispersal and for survival, often for extended periods of time, in unfavorable conditions.

Spurious parasite Organisms that parasitize other hosts passing through the human intestine and are detected in the stool after ingestion; not a true infection (ingestion of animal liver containing *Capillaria* eggs).

Standard precautions Set of precautions applied to all patients, designed to reduce the risk of transmission of microorganisms in the health care setting.

Steatorrhea Malabsorption characterized by the presence of fat in the stool (giardiasis, strongyloidiasis, cryptosporidiosis, isosporiasis).

Sterilant An agent intended to destroy all microorganisms (viruses, vegetative bacteria, fungi, and large numbers of highly resistant bacterial endospores) on inanimate surfaces.

Sterilization A procedure that effectively kills a microorganism, including bacterial spores on inanimate surfaces.

Stigmal plates Characteristic breathing apparatus in fly larvae in cases of myiasis; used to identify the specific species involved; seen at the skin opening (through which the larva receives oxygen).

Strain An intraspecific group of parasites that differs from other groups in one or more traits, including traits that might be relevant to pathogenicity, treatment, or control.

Strobila The entire chain of tapeworm proglottids, excluding the scolex and neck.

Superinfection Reinfection by a parasite that is already present in the body (*Strongyloides* and *Hymenolepis* spp.).

Swimmer's itch Dermatitis caused by skin penetration of humans by cercariae of schistosomes (normally infects birds and semiaquatic animals).

Symbiosis Close association between two different organisms; living together.

Syncope Fainting or loss of consciousness due to a temporary deficiency of blood supply to the brain (*Dracunculus* infection).

Systemic Involving the entire body.

Tachycardia Rapid heartbeat, usually more than 100 beats/min (trypanosomiasis).

Tachyzoite A rapidly multiplying stage in the development of the tissue phase of certain organisms such as *Toxoplasma gondii.*

Tenesmus Straining to defecate; may be painful and unproductive.

Tetrathyridium Second larval stage in which the scolex with its four suckers is invaginated into the anterior end of a plerocercoid type of body (tapeworm *Mesocestoides*).

Thrill *See* Hydatid thrill.

Tick paralysis A paralytic condition in the host, caused by toxic compounds found in the saliva of certain ticks.

Tinnitus Ringing or buzzing in the ear not resulting from an external source.

Toluidine blue stain Detects the cyst walls of *Pneumocystis jiroveci* as a purple color.

Transmission Transovarial transmission: passage of parasites or infective agents from the maternal body to eggs within ovaries (transmission of viral or rickettsial pathogens to larval mites or ticks).

Traveler's diarrhea Often related to giardiasis or cryptosporidiosis.

Trichinoscope A magnifying glass used in the examination of meat suspected of containing larvae of *Trichinella* spp.

Trichrome stain; Gomori trichrome Developed for histology; Wheatley's modification, developed for staining stool specimens; modified trichrome stains (10× chromotrope dye) used for staining microsporidian spores.

Trophozoite The feeding, motile stage of protozoa.

Trypanosome Slender, flagellate protozoan found in the blood of humans (*Trypanosoma* spp.); also referred to as trypomastigote (new term).

Trypomastigote Newer terminology for the trypanosome stage in human blood (*Trypanosoma* spp.).

Ulcer An open sore on the skin or mucous membrane, characterized by disintegration of the tissue and often by discharge of pus (leishmaniasis, amebiasis, *Dracunculus* infection).

Unilocular Cyst containing only one cavity.

Universal precautions Set of precautions designed to reduce risk of transmission of HIV, hepatitis B virus, and other bloodborne pathogens in the health care setting. Now referred to as standard precautions.

Urethritis Inflammation of the urethra (trichomoniasis).

Urticaria An allergic skin reaction characterized by the development of wheals and intense itching and burning sensations; onset and disappearance are often sudden (filarial infections).

Uta A mild form of New World or American cutaneous leishmaniasis caused by *Leishmania peruviana*, occurring in the high Andean valleys of Peru and Bolivia; small dermal lesions on exposed skin surfaces; the dog is an important reservoir.

Uveitis Inflammation of the uvea (the pigmented, vascular layer of the eye) (*Acanthamoeba* spp.).

Vacuole Cavity in the cytoplasm of a cell that may contain ingested bacteria, yeast cells, or debris; vacuole contents and/or morphology may be helpful in identification of some of the intestinal protozoa (*Entamoeba* spp., *Iodamoeba bütschlii*).

Vaginitis Inflammation of the vagina; prolific, irritating, green or yellowish thin discharge; there may be punctate, hemorrhagic spots (trichomoniasis).

Variant surface glycoprotein (VSG) An antigenic coat protein found on the surface of certain African trypanosomes. Different VSGs are expressed by different generations, explaining antigenic variation seen in these parasites.

Vector A biological vector is a vector such as the *Anopheles* mosquito for malarial agents or the tsetse fly for agents of African sleeping sickness, in which the agent multiplies before being transmitted to another host; a mechanical vector is a vector that conveys pathogens to a susceptible host without essential biological development of the pathogens in the vector (e.g., transfer of organisms on the feet or mouth parts of the housefly).

Vermin Parasitic insects, such as lice and bedbugs.

Vinegar eel Free-living nematode, *Turbatrix aceti*, occasionally occurring as a contaminant in laboratory solutions.

Visceral Pertaining to the internal organs of the body, especially those within the abdominal cavity.

Visceral larva migrans Tissue migration of dog and cat ascarid larvae in humans; the life cycle cannot be completed in the human host; often characterized by high peripheral eosinophilia (*Toxocara cati* and *Toxocara canis*).

Viviparous Discharging living young (*Trichinella*, filariae).

Whipworm Common name for roundworm (*Trichuris trichiura*).

WHO World Health Organization.

Winterbottom's sign Enlargement of the posterior cervical lymph nodes (African trypanosomiasis).

Xenodiagnosis Procedure allowing the feeding of laboratory-raised triatomid bugs (known to be infection free) on the blood of patients suspected of having Chagas' disease; after several weeks, the bug feces are checked for the intermediate stages of *Trypanosoma cruzi;* a type of concentration procedure.

Zooanthroponosis A zoonosis that is normally maintained by humans but can be transmitted to other vertebrates.

Zoonosis A disease of animals that is transmissible to humans (*Cryptosporidium* spp.).

Zygote The cell resulting from the fusion of male and female gametes; formed in the mosquito stomach (*Plasmodium* spp.).
